ABSTRACT

The individual characteristics of C, N, O, Na, Mg, Al, Si, and Fe on isochrones have been investigated in this study. Stellar models have been constructed for various mixtures in which the content of each element is changed up to the extreme value reported in recent studies, and the changes in isochrone shape have been analyzed for the various mixtures. To express the abundance variation of different elements with a single parameter, we have focused on the relative changes in the total number of metal ions. A review of the shape changes revealed that Na, Mg, and Al work the same way in stellar models, similar to the well-known fact that C, N, and O have the same reactions in the stellar interior. In addition, it was found that in high-metallicity conditions the influence of Si and Fe on the red giant branch becomes smaller than that of Na, Mg, and Al closer to the tip. Furthermore, the influence of Fe on the main sequence is larger than that of Na, Mg, Al, and even Si.

Key words: globular clusters: general – Hertzsprung–Russell and C–M diagrams – stars: abundances – stars: evolution – stars: interiors – stars: low-mass

1. INTRODUCTION

In almost all Galactic globular clusters (GGC), the abundance variations of individual elements have been reported. Since the study of Simoda & Iben (1968, 1970), the significance of the variation in C, N, and O abundances has been emphasized owing to their high abundances in chemical compositions (Renzini 1977; Demarque 1980; Rood & Crocker 1985). Stellar models, in which chemical composition is adopted from observations, have been constructed for comparison studies (e.g., Vandenberg 1985). Because chemical anomalies of various other elements and anti-correlations of CNONa and MgAl in GGCs have been reported (Osborn 1971; Cannon et al. 1998; Gratton et al. 2001; Cohen et al. 2005; Carretta et al. 2009a, 2009b; Lee et al. 2013), it has become more important to consider observational results. For various other elements, the effects on stars of the abundance variations have been investigated (e.g., Dotter et al. 2007; VandenBerg et al. 2012). Furthermore, some studies suggest scenarios for explaining the general abundance pattern present in the stars of GGCs, including chemical compositions with positive variations in C, N, Na, negative variations in O (Salaris et al. 2006; Cassis et al. 2008; Pietrinveni et al. 2009; Ventura et al. 2009), positive variations in Al, and negative variations in Mg content (Cassis et al. 2013).

Spectroscopic data of some GCCs show substantially more variations in the contents of a few elements than those previously recognized. For example, abundance variations of Al above 1.0 dex in [Al/Fe] have been reported in the stars of NGC 2808 and NGC 6752. It has been generally considered that changes in the content of less abundant elements such as Na and Al cause only minor effects on stellar evolution (e.g., VandenBerg et al. 2012). However, their abundance variations up to extreme values reported by recent observations may have considerable impacts on stellar evolution.

We have chosen eight elements, including C, N, O, Na, Mg, Al, Si, and Fe, to investigate cases in which their extreme values are reached, based on the values reported in previous studies. For various contents of these individual metals, stellar models and isochrones are constructed to analyze their effects and physical changes. In this study, we focus on the variation in total particle number of metal ions, and we present the changes and shifts of isochrones in a systematic way. The changes in the isochrone shape versus the relative number variation of metal ions are investigated and the results indicate that the behaviors of Na, Mg, and Al are similar in the stellar interior. Thus, these three elements can be considered as a group, which is similar to the well-recognized group of C, N, and O. Moreover, the influence of Fe on isochrones differs from those of other metal elements.

The details of the stellar model constructions are given in Section 2. The method of presenting the isochrone characteristics for systematic comparison is discussed in Section 3. Section 4 presents the results and analysis based on the isochrone shape change in terms of the changes in the total numbers of metal ions. Further discussion and a summary are given in Sections 5 and 6, respectively.

2. STELLAR MODEL CONSTRUCTION

2.1. Code and Input Physics

Stellar evolutionary models were constructed by using a version of the Yale Stellar Rotational Evolution Code (YREC), which is a standard stellar evolutionary code utilized for Y² isochrones (Yi et al. 2001, 2008; Kim et al. 2002). The models in this study are compatible with the Y² isochrone set, although two updates have been made in the computation. First, the reference solar mixture of Grevesse & Sauval (1998) was used rather than that of Grevesse & Noels (1993) used for the Y² isochrone projects. Although recent studies on the solar mixture have been conducted (Asplund et al. 2005, 2009; Lodders et al. 2009; Caffau et al. 2011; von Steiger & Zurbuchen 2016), studies of helioseismology and neutrinos prefer the higher metallicity of mixtures reported in older studies. Thus, the solar mixture of Grevesse & Sauval (1998) was chosen for this work. As VandenBerg et al. (2012) stated, the results in this type of differential study are not affected by the selection of the reference mixture. Second, the OPAL equation of state (OPAL EOS) was updated to its later version...
(Rogers et al. 1996). The change associated with the two updates is less than the typical observational error (Beom 2014). Table 1 summarizes the input physics employed for the computations in this work.

For clarity, the following two points are worth mentioning. First, the cosmic chemical enrichment, specifically \( \Delta Y/\Delta Z \), was considered in the computation of the reference isochrones. In the comparison isochrones, however, to focus on the effects of abundance changes of the individual elements, the He content was kept constant even though the total metal abundance \( Z \) was changed. This treatment is discussed further in the following subsection. Second, the stellar models in this work were constructed assuming that the ratio between metal contents in a mixture does not change during the evolution of a star. The surface chemical mixture, which is accessible through spectroscopic observations, is the integrated result of various physical mechanisms such as dredge-up, diffusion, and dynamics in the stellar atmosphere. However, our knowledge of these physical processes for each metal element is still rather limited. Because these physical processes have not been included, the ratio between metal contents in a mixture did not change during the evolution of the stellar models.

### 2.2. Construction of Stellar Models and Isochrones

The ranges of mass and metallicity for the stellar model construction were set for globular clusters in our Galaxy. The metallicity range of \([\text{Fe}/\text{H}] = -2.173 \sim -0.375 \) \((Z = 0.0002 \sim 0.012)\), which extends slightly beyond the usual range, was adopted. Including a cosmic primordial He abundance of 0.23 and a \( \Delta Y/\Delta Z \) value of two, the chemical compositions for the reference models are summarized in Table 2. For isochrones of 9 Gyr and older with this metallicity, the mass range was chosen as \( 0.7 \sim 1.1 \, M_\odot \), with 0.05 \( M_\odot \) increments. Considering the globular clusters in our Galaxy, the mixture of Grevesse \& Sauval (1998) with \( \alpha \) elements enhanced by 0.3 dex was adopted as the reference mixture for this work. The ratios of \( \alpha \) elements were taken from VandenBerg et al. (2000).

To focus on the effects of each element clearly, the abundance of each specific element was changed individually. We chose to fix all of the other elements except for H. For enhancement of a specific element, for example, the content of H is decreased by the increment of the target element. This causes the stellar model to have slightly higher \( Z \) and \([\text{Fe}/\text{H}]\). However, any change shown in a model was confirmed beforehand to be attributed primarily to the abundance change of the target element rather than to the associated change in the \( \Delta X/\Delta Z \) value. Because the relative variation in \( X \), i.e., \( \Delta X/\Delta Z \), is very small, the changes in the value of \([\text{Fe}/\text{H}]\) in this work are also very small, at less than 0.01. The net effect of the increased metal and the decreased H combined is an overall enhancement of opacity throughout the stellar interior, which causes the tracks to shift toward the lower temperature. Even though H is the most important opacity source in the stellar interior, the changes in the \( \Delta X/\Delta Z \) value are not large enough to compensate for the opacity change due to the increased metal content. The treatment of this work produces tracks comparable to those produced by VandenBerg et al. (2012), in which \([\text{Fe}/\text{H}]\) and \( Y \) were fixed.

The isochrones were generated by utilizing the method developed for the third version of \( Y^2 \) isochrone projects. Each track was divided into several parts based on the key equivalent evolutionary phases (EEP) in the evolution, the zero-age main sequence, the main-sequence turnoff point (MSTO), the base of the giant branch (the base of GB), the bumps on the GB, and the GB tip. In each part between the key EEPs, numerous secondary EEPs were assigned on the basis of the track length on the log \( T_{\text{eff}} \) versus log \( L \) diagram. Isochrones were generated by interpolating tracks at the same secondary EEPs.

### 2.3. Abundance Variations

The eight elements selected for this study, C, N, O, Na, Mg, Al, Si, and Fe, are either abundant metals in the stellar chemical makeup or elements having significant abundance variation according to recent observations of the stars in GGCs. Their abundance variations were taken from the extreme values, or the mean values of sub-population stars in the observed globular clusters. To compare the effects of Fe and Si directly, the abundance variation for Fe was chosen to be the same as that of Si. Table 3 shows the target elements, their variation, and the references. For N, O, and Al, of which the variations are quite large, the intermediate value cases were included. The various cases in this study are summarized in Table 4. The first column in the table lists the cases, with the name consisting of the atomic symbol for the element changed and the amount of the change in \([m/\text{Fe}]\) with respect to the reference mixture. For example, \( C - 0.5 \) indicates that the abundance of C is decreased by 0.5 dex in \([\text{C}/\text{Fe}]\) with respect to the reference mixture. For example, the remaining columns of the table present the chemical composition set in the case of \( Z_{\text{ref}} = 0.001 \), where the subscript ref. refers to the reference model. For the second and the third columns, the metallicities of each case are expressed in \( Z \) and \([\text{Fe}/\text{H}]\). As mentioned in

### Table 1

| Input Physics          | Source                                      |
|------------------------|---------------------------------------------|
| Solar mixture          | Grevesse \& Sauval (1998) \((Z/X = 0.0230)\) |
| Abundances and ratio of \( \alpha \) elements | \([\alpha/\text{Fe}] = 0.3 \) (VandenBerg et al. 2000) |

|               |              |                                 |            |            |            |            |            |            | 6.546 |

Notes.

* The metallicities for the cases of $Z_{\text{ref}} = 0.0010$ ([Fe/H]$_{\text{ref}} = -1.473$). The abundance variation is so slight that the metallicities seems to be unchanged for most of the cases.

b The abundances for the cases of $Z_{\text{ref}} = 0.0010$ on the scale of log $N_{\text{fe}} = 11.00$; $A_{\text{m}} = \log N_{\text{m}}/N_{\text{fe}} + 11.00$.

c The mass fraction for the heavier elements than He.

Section 2.2, the total metallicities are slightly modified as well. The last eight columns show the abundances by number for the eight target elements; these values were calculated on the scale of log $N_{\text{fe}} = 11.00$.

3. ANALYSIS METHOD: A SYSTEMATIC PRESENTATION OF THE CHANGES IN ISOCHRONE SHAPE

In previous studies, such as VandenBerg et al. (2012) and Pietrinveni et al. (2009), the effects of abundance variation of individual elements have been discussed extensively. The abundance variations of an element mainly influence the opacity and energy generation, resulting in shape changes of evolutionary tracks and isochrones. To present these effects quantitatively, we examined the differences in the locations of MSTO and GB, and the length of sub-GB between isochrones.

The net effect on isochrones is measured by considering an isochrone as a whole, from the main sequence (MS) to the red giant branch (RGB) tip. It is common knowledge that the influence of C, N, and O is mainly on the MS phase and that of Na, Mg, Al, Si, and Fe is mainly on the RGB. This simple description, however, is not sufficient. When the metallicity is sufficiently high in the MS stars to create effective temperatures of less than about 3.80 in log $T_{\text{eff}}$, Na, Mg, Al, Si, or Fe can affect the opacity significantly in the outermost parts of these stars. As a result, a metal-rich star can be influenced by the effect of this high surface opacity during its entire lifetime. In Figure 1, this phenomenon is clearly indicated by a comparison of the upper and bottom panels, which show isochrones with metallicities of [Fe/H] = −1.473 and −0.618, respectively. The colored lines represent isochrones with various abundance variations. Contrary to that in the upper panel, the high-metallicity isochrones in the bottom panel show noticeable shifts of the MS that are comparable to those of the RGB. Moreover, such modifications on the MS phase are comparable to, or more than, those caused by C, N, or O. Therefore, the changes in the locations of both the MS and RGB were estimated for all elements considered. Because the effect of the abundance variation can differ depending on the locations along an RGB, the shifts in various locations were estimated from the RGB base to the tip.
In this study, the changes in the shapes of isochrones are presented in three parameters: the MS location, RGB location, and length of the sub-GB. In determining the difference in MS location between isochrones, the hottest points were selected as the MSTOs. The RGB locations were compared at four different levels set at points 1.5, 3.0, 4.5, and 6.0 brighter in magnitude than the MSTO. The dimmest and the brightest levels among these locations represent the RGB base and tip, respectively. Except for the cases of C, N, and O variations, the location differences are considered only in terms of effective temperature rather than luminosity because the changes in the latter were small in the mass and metallicity ranges of this study. For the length of the sub-GB, the difference in effective temperature between the MSTO and the base of the RGB were estimated. The base of the RGB was set to the location 1.5 mag brighter than that of the MSTO. It should be noted that the length of the sub-GB in this study is commonly used for age estimation of globular clusters (Sarajedini & Demarque 1990; Vandenberg et al. 1990, 2013).

4. RESULTS

In this section, we analyze the changes in isochrone shape for mixtures with abundance variations of individual elements. We focus on the parameter, namely, the relative changes in the total number of metal ions introduced by the variation of the individual elements. Because these changes are approximately the same for Mg $^{+0.2}$, Fe $^{+0.4}$, and Al $^{+1.5}$, the isochrones of these three mixtures almost overlap in the Hertzsprung–Russell diagram (HRD). When the isochrone shape change is reviewed in terms of this parameter, it is found that Na, Mg, and Al have similar effects. It is widely accepted that C, N, and O can be considered as one group and that the total sum of their content can be utilized for describing the effect on stellar structure and evolution (e.g., Simoda & Iben 1970; Renzini 1977; Demarque 1980; Vandenberg 1985). The newly identified group of Na, Mg, and Al in this paper can be considered similarly. In addition, Fe shows distinctive characteristics from other elements. As that of Si, the influence of Fe is less than those of Na, Mg, and Al near RGB tip, in metal-rich stars. In MS stars, however, the influence of Fe is much larger than those of Na, Mg, Al, and even Si.

4.1. Influence of Extreme Variation in Abundance

It has been considered that the less abundant metals such as Al have limited influence on stellar evolution. However, huge increases or decreases reported by recent observations may have considerable impacts. For Al $^{+1.5}$, which is the extreme case based on the values from observations, the isochrone shows noticeable changes with respect to the reference isochrone. The isochrones of Mg $^{+0.2}$, Al $^{+1.5}$, and Fe $^{+0.4}$ show almost the same shape so that their lines nearly overlap.

Figure 2. From the sub-GB to RGB bump of the 12 Gyr isochrones for six cases are given, namely, reference, Na $^{+0.5}$, Mg $^{+0.2}$, Al $^{+1.5}$, Si $^{+0.4}$, and Fe $^{+0.4}$. The order of the mixture in the legend was chosen according to the shift of the isochrones with respect to the reference isochrone. The isochrones of Mg $^{+0.2}$, Al $^{+1.5}$, and Fe $^{+0.4}$ show almost the same shape so that their lines nearly overlap.
large as that of Al + 1.5. The amount of Na increase that makes a noticeable change in isochrone shape will be discussed in Section 5.1.

For the three cases of Al + 1.5, Mg + 0.2, and Fe + 0.4, whose isochrones overlap in Figure 2, the actual changes in the total number of metal ions are similar even though the abundance variations presented in dex differ significantly, namely +1.5, +0.2, +0.4. Thus, we focused on the relative changes in the total number of metal ions (ΔNJ/NZ,ref) to describe the abundance variation in the study of the effect of individual elements on isochrones.

The unit of dex ([m/Fe]) is generally used to express abundance variation. However, when comparing cases involving different elements, values expressed in [m/Fe] can be misleading because it is a value scaled for the solar mixture. The mixture with enhanced C by 0.5, for example, shows more variation in the number of metal ions than that shown by the mixture with enhanced N by 0.8 because C is more abundant than N in the solar mixture. For this reason, the abundances of abundant elements such as O, Mg, and Si, have mainly been considered in the chemical composition of stars (Rood & Crocker 1985; VandenBerg et al. 2012). Another issue is that the value is log scaled. For example, a comparison of mixtures with N enhanced by 1.6 and that by 0.8 in dex revealed a twofold difference in number although the actual change in the number of N particles differed about fourfold. Thus, to express the abundance variation using a single parameter, the relative changes in the total number of metal ions is examined in this study.

4.2. Abundance Variation and Net Effect

To express the abundance variation of various elements in the same parameter domain, the chosen parameter is the relative change in particle number with respect to the reference mixture. Because its value is relative to the reference mixture, this parameter is independent of the total metallicity. For example, when the parameter is +0.3, the total number of metal ions in the comparison model is enhanced by +30% over that in the reference model. The parameter is presented as

\[ \Delta N_Z/N_{Z,\text{ref}} = \frac{N_{Z,\text{mod}} - N_{Z,\text{ref}}}{N_{Z,\text{ref}}} \]  

where \( N_z \) is the abundance in number for all metal elements, and the subscripts ref. and mod. indicate the stellar models before and after the modification, respectively. The parameter can be calculated in the following equation with variation in dex and the number fraction in the reference mixture:

\[ \Delta N_Z/N_{Z,\text{ref}} = f_{m,\text{ref}} \times (10^{\Delta [m/Fe]} - 1) \]  

where \( m \) is a target element having a change in abundance, and \( f_{m,\text{ref}} \) and \( \Delta [m/Fe] \) are the number fraction in the reference mixture and the variation in dex, respectively; the other variables are the same as those in Equation (1). The values of the parameter for the cases in this work are summarized in Table 5. When the abundance change is expressed with the parameter, the degree of the shape change of the isochrones appears to be linearly related to the abundance variation.

### Table 5

| Mixture       | ΔNJ/NZ,ref (%) |
|---------------|----------------|
| Reference     | 0.00           |

**Note.** The relative variation in total number of metal ions, expressed in percentage. Furthermore, this parameter is independent of the total metallicity.

4.3. Grouping of Elements and Their Abundance Sum

The impact of abundance variation in Na, Mg, and Al contents is shown in Figure 3. The figure presents the difference in sub-GB length for three different metallicities in terms of the abundance variation, which was introduced in the previous section. In the figure, the points appear to form a straight line. This indicates that the changes in isochrone shape are linearly correlated with the relative changes in the number of metal ions regardless of the choice of element among Na, Mg, or Al. That is, when the number variations are the same, the isochrones for the three elements have similar shapes. The same is true for the shifts of MS and RGB, which is discussed further in the following subsection.

This correlation can be described as behavior that the three elements affect similarly in stellar interior models. The abundance change for these elements affects the interior models mainly through the opacity. As reported by VandenBerg et al. (2012), the abundance change of these elements increases the opacity in the similar temperature ranges of the stellar interior. These elements have similar atomic structures; therefore, their ionization potential is similar, and they donate a similar number of electrons in a certain physical condition. Therefore, the opacity is similarly changed when the abundance changes of these elements are the same. The effect on the energy generation, however, is very limited. Unlike C, N, and O, the impact of the elements on the energy generation is through only changes of the physical condition associated with the structural changes.

It is widely accepted that C, N, and O have similar roles and influence in a star and that the degree of the effects depends on \([C + N + O]/Fe\). Figure 4 is the same as Figure 3, except for the elements. As expected, a linear relation can be detected in each panel even though the linearity appears to be weaker in Figure 4. This may have occurred because these elements are related to nucleosynthesis as well as opacity, whereas the group of Na, Mg, and Al is directly related only to opacity. Figure 5 plots the shifts of MSTO in both effective temperature (upper panels) and brightness (lower panels). In all panels, a linear
Figure 3. For isochrones of various Na, Mg, or Al contents, the number variation of metal elements vs. the degree of net effect represented by the changes in the length of the sub-GB, at three different metallicity conditions is given. The $x$ axis is the number variation of metal ions, whereas the $y$ axis is the length of the sub-GB. The seemingly linear relation may indicate that Na, Mg, and Al have similar behavior in the stellar structure.

Figure 4. Same as Figure 3, except for isochrones of various C, N, and O contents. Linearity can be found in each panel, which means C, N, and O have similar behavior in stellar models.

Figure 5. For isochrones of various C, N, or O contents, the number variation of metal elements vs. the degree of net effect represented by the shifts of the MSTO is shown for three different metallicity conditions. The $x$ axis is the number variation of metal ions, and the $y$ axis is the shift of the MSTO on the HRD. A linear relation can be seen in all panels, as is shown in Figure 4.
relation can be found. This again means that the degree of the net effect is the same when the number of the target element is changed by the same amount regardless of which element is chosen among C, N, and O.

In summary, it appears that Na, Mg, and Al can be considered as one group. Similar to \([\text{C} + \text{N} + \text{O}/\text{Fe}], [\text{Na} + \text{Mg} + \text{Al}/\text{Fe}]\) determines the degree of the effect on stellar models. Therefore, no significant change can be expected in stars in which the sum of Na, Mg, and Al contents is not significantly changed. For example, in stars of the AGB phase the Mg–Al reaction reduces the Mg and increases the Al contents. Thus, next-generation stars polluted by the winds from AGB stars show Mg–Al anti-correlation. Because the sum of Mg and Al contents is not significantly changed, however, the effect associated with the abundance variation in these contents may be very limited.

4.4. Distinct Characteristics of Si and Fe from Other Elements

In this section, we focus on the characteristics of Fe and Si that distinguish them from the other elements considered in this work. It is considered that Si and Fe generally behave in a manner similar to other metals, especially Mg, in stellar models (e.g., VandenBerg et al. 2012). In particular, Si has been considered to be similar to Mg owing to their roles in stellar models and their high abundance. However, Dotter et al. (2007) reported that the influence of Si on opacity becomes smaller than that of Mg at low temperatures. In the present study, the effect of Fe, as well as Si, was shown to be lower than that of other metals at low temperatures. In addition, the influence of Fe is much larger than those of Na, Mg, Al, and even Si.

In high-metallicity conditions, the influence of Fe as well as Si decrease near the RGB tip where effective temperature is lower. Figure 6 shows the RGB of the 12 Gyr isochrones with \([\text{Fe}/\text{H}] = -0.866\). In the right panel, unlike others, the isochrones of \(\text{Si} + 0.4\) and \(\text{Fe} + 0.4\) are inclined toward the reference isochrone as they approach the RGB tip. The same is shown in Figure 7, which also shows the location differences of the RGBs with respect to the abundance variation. The four columns of the panels represent the four different values of metallicity, and the three rows represent cases with different locations of RGB shift measurement. In the left panels of the figure, the points of Si and Fe are located near the line formed by the points of Na, Mg, and Al. In the upper and right panels, however, which represent the shift of RGB measured at the brighter points along RGB in addition to higher metallicity, the two points appear not to be associated with the linear relation formed by the other points. For the abundance variations of \(\text{Si} + 0.4\) and \(\text{Fe} + 0.4\), the shift of RGB was expected to be increased with the points located farther below. The fact that this did not occur can be interpreted as the lesser influence of Si and Fe in stars with low effective temperature, i.e., for higher metallicity and positions closer to the RGB tip. Furthermore, this effect is stronger for Si than Fe. The influence of each element on opacity differs in various temperature and density according to its atomic structure. Thus, it is expected that the influence of Na, Mg, and Al might differ from each other only in cases with higher metallicity. However, the metallicity is beyond the usual metallicity range of globular clusters in our Galaxy (above about \([\text{Fe}/\text{H}] = -0.5\)). In comparison, the reduced influence of Si and Fe can be seen in the RGB stars of a metal-rich cluster above \([\text{Fe}/\text{H}] = -1.0\).

The influence of Fe near the MSTO is greater than that of Na, Mg, Al, and even Si. Figure 8 shows the shift of the MSTO as a function of the abundance variation. The point of \(\text{Fe} + 0.4\) is located far below the line formed by other points. This indicates that more changes of the MSTO location than that of the other elements is expected when the degree of the abundance variation is the same. Although the abundance variation of \(\text{Fe} + 0.4\) is similar to that of \(\text{Mg} + 0.2\) and \(\text{Al} + 1.5\), the MSTO of the isochrone shift of \(\text{Fe} + 0.4\) is twice that of the others. On the contrary, the point of \(\text{Si} + 0.4\) appears to be on the line formed by the points of the cases for Na, Mg, and Al. In the inner part of a stellar model, the opacity peak associated with Fe is at a different temperature range from that of the other elements; the opacity peaks of Na, Mg, Al, and Si occur almost in the same region (VandenBerg et al. 2012).

These characteristics are shown in Figure 9, which is the same as Figure 3, except for the addition of Fe and Si cases. In all panels of the figure, the points of \(\text{Fe} + 0.4\) and \(\text{Si} + 0.4\) do not appear to be associated with the linear relation of Na, Mg, and Al. The length of the sub-GB for \(\text{Fe} + 0.4\) and \(\text{Si} + 0.4\) is modified less because of the lower influence of Fe and Si on the RGB. Additionally, \(\text{Fe} + 0.4\) shows a significant shift of the MSTO, which is in the same direction as the RGB; thus, the change in the length of the sub-GB is less than that in other cases.

5. DISCUSSION

The first subsection discusses abundance variations of less abundant metals. The previous results show that their extreme variations can cause considerable change in isochrone shape. The lower limits of abundance variations are discussed based on the abundance variations and associated shape changes in the isochrone. Furthermore, the results of the Section 4 indicate that the two parameters, specifically \([\text{C} + \text{N} + \text{O}/\text{Fe}]\) and \([\text{Na} + \text{Mg} + \text{Al}/\text{Fe}]\), are key parameters in stars whose mixtures have CNONa and MgAl anti-correlations. Thus, the
Figure 7. For isochrones of various Na, Mg, and Al mixtures, the number variation of metal elements vs. the degree of net effect represented by the shifts of the RGB is given for three different metallicity conditions. The $x$ axis is the number variation of metal ions, and the $y$ axis presents the shifts of the RGB measured at the various locations on the HRD. The influence of Si and Fe is reduced more than that of other elements as the metallicity increases and the upper location of the RGB is approached.

Figure 8. Same as the upper panels of Figure 5, except for isochrones of various Na, Mg, Al, Si, and Fe cases. The influence of Fe near the MSTO is noticeably higher than that of the other elements. However, Si appears to follow the trend of Na, Mg, and Al.
last subsection discusses the implication of the new group of Na, Mg, and Al in evolutionary point of view.

5.1. Lower Limits of Abundance Variation

To determine the limiting value in the abundance variation that causes noticeable changes in the isochrones, the length of the sub-GB was investigated. It was assumed that the typical error of the age estimation utilizing the length of the sub-GB for a globular cluster is about 0.5 Gyr (Vandenberg et al. 2013). For C and N, the enhancement of about 0.5 dex in [C/Fe] or about 1.0 dex in [N/Fe] cause a noticeable increase in the age estimation. Because of their low abundances in the reference mixture, however, any amount of depletion in the abundance of these elements cannot produce isochrones that resemble those that are 0.5 Gyr younger. Conversely, both enhancement and depletion are attainable for O.

For Na and Al, this factor depends on the metallicity. Metallicities lower than [Fe/H] = −1.0, [Na/Fe] = 1.3 dex and above produce an isochrone appearing 0.5 Gyr younger, which corresponds with the enhancements of Δ[Na/Fe] = +1.0 with respect to the reference mixture. For Al, the value is [Al/Fe] = 1.2 dex and above, which is the same as Δ[Al/Fe] = +1.5 with respect to the reference mixture. For a metallicity higher than [Fe/H] = −1.0, the value is about [Na/Fe] = 1.1 dex and above, which corresponds to Δ[Na/Fe] = +0.8. And the value is [Al/Fe] = 0.9 dex and above, which is Δ[Al/Fe] = +1.2. Because of the low abundance, an isochrone that is 0.5 Gyr older cannot be generated by any amount of depletion in Na and Al contents. For Mg, however, both enhancement and depletion may be considered.

As discussed in Section 4.3, for elements in a group, the variation in the total sum rather than in individual variations is an important parameter. For Δ[C + N + O/Fe], an abundance variation of about Δ[C + N + O/Fe] = +1.5 and greater can produce recognizable changes in age estimation. Depending on metallicity, the variations beyond Δ[C + N + O/Fe] = +2.0 and Δ[C + N + O/Fe] = +3.0 in the lower metallicities of [Fe/H] = +0.3 and Δ[C + N + O/Fe] = +3.0 in the higher metallicities of [Fe/H] = −1.0 are considerable.

5.2. Implication of the General Abundance Pattern

The fact that Na, Mg, and Al can be considered as a group, such as the case of CNO, has an important implication on the studies of the GGCs that show CNONa and MgAl anti-correlations. According to the anti-correlations, the contents of C and N of second-generation stars is enhanced, whereas that of O is depleted. Similarly, the abundance variation of Na and Al is opposite that of Mg. When the changes in the content of an individual element in a group cancel out, the resulting effect may be less than expected otherwise. For example, some second-generation stars have a mixture enhanced by 0.8 dex of Na and 1.0 dex of Al and depleted by 0.3 Mg (Carretta et al. 2009a). The total abundance change is −0.0008 in ΔN_Z/N_Z,ref and −0.010 in terms of Δ[Na + Mg + Al/Fe]. Therefore, no significant change is expected in the shape of its isochrone. This expectation, similar to that reported by Cassis et al. (2013), can serve as an example of the case mentioned in the last part of Section 4.3. For the case of Salaris et al. (2006), second-generation stars have a mixture of 0.6 dex increase of C, 1.8 dex increase of N, and 0.8 dex decrease of O. The actual changes in total are 2.24 in ΔN_Z/N_Z,ref and 0.585 in Δ[C + N + O/Fe]. Because of the huge increase in N, the total variation is very large even after some cancellation. Therefore, the isochrones for these second-generation stars differ significantly from those for first-generation stars.

For an isochrone shape on the theoretical HRD, O is commonly taken as the representative among CNO because it is the most abundant element. Similarly, Mg can represent Na, Mg, and Al. Thus, instead of all six elements of C, N, O, Na, Mg, and Al, only two elements of O and Mg need to be considered. For the first example, the isochrone for Δ[Mg/Fe] = −0.010 is the same as that with variations in the content of all three elements; the case of Δ[O/Fe] = 0.674 is the same as that in the second example.

6. SUMMARY

The abundance variations of individual elements have been reported in stars of GGCs; their effects on stellar evolution and isochrones have been investigated for extreme cases. In this study, stellar models and isochrones were constructed with mass and metallicity ranges for GGCs of [Fe/H] = −2.173 ∼ −0.375 (Z = 0.0002 ∼ 0.012) and 0.7 ∼ 1.1 M_☉.

In the analysis of its effect of an individual element, the changes in the total number of metal ions introduced by the abundance variation is shown to be a key parameter. The changes of the isochrone shape is expressed in terms of the change in the total number of metal ions. Analysis of the isochrones for various elements revealed that a few elements...
have similar roles in stellar models. In particular, Na, Mg, and Al can be considered as one group as in the case of C, N, and O. Therefore, the abundance variations can be considered as variations of [Na + Mg + Al/Fe] and [C + N + O/Fe].

The influence of Si and Fe on the MS and RGB differed from those of Na, Al, and Mg. Specifically, the influence of Si and Fe on the RGB became smaller than that of Na, Mg, and Al in a star with low effective temperature. Thus, the influence of Si and Fe decreases as the metallicity increases and in points ascending along the RGB. Additionally, the influence of Fe on the MS is larger than that of Na, Mg, Al, and even Si.

To produce noticeable change in isochrones, the variation in the content of elements should be larger than certain values. Depending on the metallicity, these values are about [Na/Fe] = 1.1 dex or more, [Al/Fe] = 0.9 dex or more with the enhancements of about 0.5 dex in [C/Fe], and about 1.0 dex in [N/Fe]. This can also be presented as Δ[C+N+O/Fe] = +0.15 and Δ[Na+Mg+Al/Fe] = +0.11.

According to the general abundance pattern of second-generation stars, the abundances of the relatively less abundant elements such as C, N, Na, and Al were highly enhanced while those of the abundant elements such as O and Mg were depleted (e.g., Carretta et al. 2009a, 2009b). However, because Na, Mg, and Al can be considered as a single group, similar to the case of C, N, and O, the abundance sum of NaMgAl can also be utilized in the studies examining the effect caused by their abundance variation in stellar models.
