ABSTRACT

To examine whether or not high-ionization nuclear emission-line regions (HINERs) in narrow-line regions of active galactic nuclei are dusty, we focus on two high-ionization forbidden emission lines, [Fe \textsc{vii}] λ6087 and [Ne \textsc{v}] λ3426. We perform photoionization model calculations to investigate possible dependences of the flux ratio of [Fe \textsc{vii}] λ6087/[Ne \textsc{v}] λ3426 on various gas properties, in order to investigate how useful this flux ratio is to explore the dust abundances in HINERs. Based on our photoionization model calculations, we show that the observed range of the flux ratio of [Fe \textsc{vii}] λ6087/[Ne \textsc{v}] λ3426 is consistent with the dust-free models, while it cannot easily be explained by the dusty models. This suggests that iron is not depleted in HINERs, which implies that the HINERs are not dusty. This result is consistent with the idea that the HINERs are located closer than the dust-sublimation radius (i.e., the inner radius of dusty tori) and thus can be hidden by dusty tori when seen from an edge-on view toward the tori, which is also suggested by the AGN-type dependence of the visibility of high-ionization emission lines.

Key words: galaxies: active — galaxies: ISM — galaxies: nuclei — galaxies: Seyfert — quasars: emission lines

1. INTRODUCTION

The narrow-line region (NLR) is one of the fundamental ingredients of active galactic nuclei (AGNs), such as Seyfert galaxies, and thus its physical and chemical properties have been studied intensively up to now (see Osterbrock & Mathews 1986 for a review). Since the presence of dust grains significantly affects emission-line spectra in several ways, the question has often been discussed as to whether or not dust grains survive in the NLRs. The chemical composition of the gas phase is modified by the depletion of refractory elements into the grains. Electrons photoelectrically ejected from the grains heat the gas, while electron-grain collisions cool it. The dust opacity modifies the transfer of the ionizing continuum that irradiates gas clouds in NLRs. Therefore, the knowledge of dust abundances is required to interpret observed emission-line spectra of NLRs (see, e.g., Ferguson et al. 1997a).

There is some evidence suggesting the presence of dust grains in NLRs. Asymmetric narrow emission-line profiles may suggest the presence of dust grains in the gas (e.g., Heckman et al. 1981; De Robertis & Osterbrock 1984; Whittle 1985a, 1985b). In partially ionized regions in NLRs the depletion of some refractory elements is suggested by the weakness of the [Ca \textsc{ii}] emission (e.g., Kingdon, Ferland, & Feibelman 1995; Ferguson et al. 1997a) and by comparing the intensity of near-infrared [Fe \textsc{ii}] emission lines with that of [O \textsc{ii}] λ6300 (e.g., Mouri et al. 1989; Simpson et al. 1996; Alonso-Herrero et al. 1997; Mouri, Kawara, & Taniguchi 2000) and with that of [P \textsc{ii}] 1.188 μm (e.g., Oliva et al. 2001; Rodriguez-Ardila et al. 2002). Some resonance lines have been observed to be very weak, which seems also to be a result of line transfer effect within dusty gas (e.g., Kraemer et al. 2000). These considerations naturally raise the question of whether the NLR is ubiquitously dusty.

The innermost region of NLRs, which is irradiated by high-photoionizing flux, is thought to be rather high velocity, highly ionized, dense gas clouds (e.g., De Robertis & Osterbrock 1984; Murayama & Taniguchi 1998a, 1998b; Barth et al. 1999; Tran, Cohen, & Villar-Martin 2000; Nagao, Taniguchi, & Murayama 2000b; Nagao, Murayama, & Taniguchi 2001a, 2001b). Since the gas clouds in this region can radiate very high ionization emission lines, such as [Ne \textsc{v}], [Fe \textsc{vii}], and [Fe \textsc{x}] (the so-called coronal lines), such regions are called “coronal line regions” or “high-ionization nuclear emission-line regions” (HINERs, Binette 1985; Murayama, Taniguchi, & Iwasawa 1998). Nussbaumer & Osterbrock (1970) reported that the gas-phase abundance of iron that is estimated by using the emission-line flux ratio of [Fe \textsc{vii}] λ6087/[Ne \textsc{v}] λ3426 is close to the solar value. This means that the iron is not depleted significantly, because of the absence of grains in HINERs. However, Ferguson, Korista, & Ferland (1997b) noted that the flux ratio of [Fe \textsc{vii}] λ6087/[Ne \textsc{v}] λ3426 depends on physical properties of gas clouds, and thus it may be inappropriate to use this ratio as an indicator of the gas-phase iron abundance. They proposed alternative indicators of the gas-phase abundances of refractory elements, using some near-infrared high-ionization lines, such as [Ca \textsc{ii}] 2.32 μm, and then suggested that the HINERs seem to be dust-free (see also Ferguson et al. 1997a). Although their method is a robust one, it can be applied only to very few objects, since the near-infrared high-ionization lines are hard to measure. Indeed, they applied their method only to the two Seyfert galaxies NGC 1068 and the Circinus galaxy, and they concluded that the HINERs in the two Seyfert galaxies are dust free.

To investigate whether the HINERs contain dust grains for a large sample of AGNs, we focus again on [Fe \textsc{vii}] λ6087 and [Ne \textsc{v}] λ3426. These two forbidden emission lines are thought to arise at similar regions, since their critical densities are similar (1.6 × 10^2 and 3.6 × 10^7 cm^{-3}, respectively), and the ionization potentials of Fe^{6+} and Ne^{4+} are also nearly the same (97.1 and 99.1 eV, respectively). In
addition to this advantage, it should be also a great advantage that these two emission lines are enough strong to be measured easily. Therefore, they are useful for an examination of the dust abundances in the HINERs, as long as we know some possible dependences of their emissivities on physical properties, even though they might be inappropriate to determine exact gas-phase elemental abundances, as noted by Ferguson et al. (1997b). In this paper we investigate the dependences of the two high-ionization emission lines on physical properties, based on photoionization model calculations. We then examine how these emission lines can put constraints on the issue of whether or not the HINERs are dusty.

2. DATA OF EMISSION-LINE FLUX RATIOS

To study the properties of gas clouds in HINERs, we have compiled the data of emission-line flux ratios of [Fe \textsc{vii}] $\lambda$6087/[O \textsc{iii}] $\lambda$5007 and [Ne \textsc{v}] $\lambda$3426/[O \textsc{iii}] $\lambda$5007 from the literature. The details of the data compilation are given by Nagao et al. (2001b). The number of compiled objects is 58: 34 type 1 AGNs and 24 type 2 AGNs. Here we refer to Véron-Cetty & Véron (2001) for the AGN type of each object. Note that, in this paper, the objects classified as type 1.0, 1.2, and 1.5 AGNs (including narrow-line Seyfert 1 galaxies) by Véron-Cetty & Véron (2001) are included in "type 1 AGNs," and the objects classified as type 1.8, 1.9, and 2.0 AGNs are included in "type 2 AGNs." Since we do not impose any selection criteria on our sample, this sample is neither a uniform nor a complete one in any sense. However, this does not affect the following discussion significantly, because we are not interested in statistical properties of NLR gas clouds. Rather, we focus on whether the distribution of emission-line flux ratios is consistent with that expected for dust-free or dusty cases, respectively. The compiled emission-line flux ratios are given in Table 1. We adopt an average value if an emission-line flux ratio for a certain object is given in more than one previously published paper. As for the data of the emission-line flux ratios, we do not make any reddening correction, since it is often difficult to measure the fluxes of narrow components of Balmer lines for type 1 AGNs (see, e.g., Nagao et al. 2001b). Effects of the dust extinction are discussed when necessary.

3. RESULTS

In Figure 1 we show the frequency distributions of the two emission-line flux ratios, [Ne \textsc{v}] $\lambda$3426/[O \textsc{iii}] $\lambda$5007 and [Fe \textsc{vii}] $\lambda$6087/[O \textsc{iii}] $\lambda$5007, for both the type 1 and the type 2 AGNs in our sample. The average and the 1 $\sigma$ standard deviation of these two emission-line flux ratios are $0.191 \pm 0.114$ and 0.089 $\pm$ 0.079, for the type 1 AGNs, and $0.066 \pm 0.042$ and 0.020 $\pm$ 0.015, for the type 2 AGNs, respectively. The comparison of these results between the type 1 and type 2 AGNs clearly suggests that the type 1 AGNs exhibit systematically larger ratios of both [Ne \textsc{v}] $\lambda$3426/[O \textsc{iii}] $\lambda$5007 and [Fe \textsc{vii}] $\lambda$6087/[O \textsc{iii}] $\lambda$5007 than the type 2 AGNs. We apply the Kolmogorov-Smirnov (K-S) statistical test on the data to estimate the significance of the differences in the two emission-line flux ratios between the type 1 and the type 2 AGNs. The resultant probabilities that the frequency distributions of the type 1 and type 2 AGNs come from the same underlying populations are $2.0 \times 10^{-6}$ and $5.9 \times 10^{-6}$ for [Ne \textsc{v}] $\lambda$3426/[O \textsc{iii}] $\lambda$5007 and [Fe \textsc{vii}] $\lambda$6087/[O \textsc{iii}] $\lambda$5007, respectively. It is thus confirmed that the two emission-line flux ratios are significantly larger in the type 1 than in the type 2 AGNs. This result is consistent with the previous reports by Murayama & Taniguchi (1998a) and Nagao et al. (2000b, 2001b). They concluded that these differences in the emission-line flux ratios are due to the orientation effect; i.e., the HINER is located very close to the nucleus and thus can be hidden by dusty tori if it is observed from an edge-on view toward the tori.

Contrary to the above results, the difference in the flux ratio of [Fe \textsc{vii}] $\lambda$6087/[Fe \textsc{vii}] $\lambda$3426 between the type 1 and type 2 AGNs is fairly small, as shown in Figure 2. The average and the 1 $\sigma$ standard deviation of this flux ratio are 0.523 $\pm$ 0.461 for the type 1 and 0.335 $\pm$ 0.315 for the type 2 AGNs. The average and the 1 $\sigma$ standard deviation for the entire sample (i.e., 58 AGNs) are 0.445 $\pm$ 0.415, and the median value is 0.309. Although the flux ratios of the type 2 AGNs seem to be somewhat smaller than the type 1 AGNs, the difference is not significant. The K-S statistical test

| 3C 120  | 0.104                         | 0.016                         |
| 3C 445  | 0.077                         | 0.038                         |

The resultant probabilities that the frequency distributions of the type 1 and type 2 AGNs come from the same underlying populations are $2.0 \times 10^{-6}$ and $5.9 \times 10^{-6}$ for [Ne \textsc{v}] $\lambda$3426/[O \textsc{iii}] $\lambda$5007 and [Fe \textsc{vii}] $\lambda$6087/[O \textsc{iii}] $\lambda$5007, respectively. It is thus confirmed that the two emission-line flux ratios are significantly larger in the type 1 than in the type 2 AGNs. This result is consistent with the previous reports by Murayama & Taniguchi (1998a) and Nagao et al. (2000b, 2001b). They concluded that these differences in the emission-line flux ratios are due to the orientation effect; i.e., the HINER is located very close to the nucleus and thus can be hidden by dusty tori if it is observed from an edge-on view toward the tori.

Contrary to the above results, the difference in the flux ratio of [Fe \textsc{vii}] $\lambda$6087/[Fe \textsc{vii}] $\lambda$3426 between the type 1 and type 2 AGNs is fairly small, as shown in Figure 2. The average and the 1 $\sigma$ standard deviation of this flux ratio are 0.523 $\pm$ 0.461 for the type 1 and 0.335 $\pm$ 0.315 for the type 2 AGNs. The average and the 1 $\sigma$ standard deviation for the entire sample (i.e., 58 AGNs) are 0.445 $\pm$ 0.415, and the median value is 0.309. Although the flux ratios of the type 2 AGNs seem to be somewhat smaller than the type 1 AGNs, the difference is not significant. The K-S statistical test
density of a cloud ($N_H$); and (5) the elemental composition and the dust abundance of the gas.

We adopt the SED in the form of $f_\nu \propto \nu^\alpha$ with $\alpha = 2.5$ for $\lambda > 10 \mu m$, $\alpha = -1.5$ between 10 $\mu m$ and 50 keV, and $\alpha = -2.0$ for $h\nu > 50$ keV, taking account of the SEDs actually observed in AGNs (e.g., Kosi 1978; Storch-Bergman & Pastoriza 1989, 1990; Kinney et al. 1991; see also Ho, Shields, & Filippenko 1993). Since forbidden lines arise most effectively in gas clouds with a density near their critical densities, the gas density of the [Fe vii] $\lambda 6087$ and the [Ne v] $\lambda 3426$ emitting regions are expected to be a few times $10^{17}$ cm$^{-3}$. We thus perform model runs with $n_H = 10^{6.5}$, $10^{7.0}$, and $10^{7.5}$ cm$^{-3}$. As for the ionization parameter, we investigate models with $U = 10^{-2.5}$, $10^{-2.0}$, and $10^{-1.5}$, although the ionization parameter of HINERs is thought to be rather high, that is to say, $U \gtrsim 10^{-2}$ (e.g., Murayama & Taniguchi 1999b; Nagao et al. 2001b).

For the dust-free models we set the gas-phase elemental abundances to be the solar ones, taken from Grevesse & Anders (1989) with extensions by Grevesse & Noels (1993). The adopted gas-phase elemental abundances are as follows: H: 1.00, He: $1.00 \times 10^{-6}$, Li: $2.04 \times 10^{-9}$, Be: $2.63 \times 10^{-11}$, B: $7.59 \times 10^{-10}$, C: $3.55 \times 10^{-4}$, N: $9.33 \times 10^{-5}$, O: $7.41 \times 10^{-4}$, F: $3.02 \times 10^{-8}$, Ne: $1.17 \times 10^{-4}$, Na: $2.06 \times 10^{-6}$, Mg: $3.80 \times 10^{-5}$, Al: $2.95 \times 10^{-6}$, Si: $3.55 \times 10^{-5}$, P: $3.73 \times 10^{-7}$, S: $1.62 \times 10^{-5}$, Cl: $1.88 \times 10^{-7}$, Ar: $3.98 \times 10^{-6}$, K: $1.35 \times 10^{-7}$, Ca: $2.29 \times 10^{-6}$, Sc: $1.58 \times 10^{-7}$, Ti: $1.10 \times 10^{-7}$, V: $1.05 \times 10^{-8}$, Cr: $4.84 \times 10^{-7}$, Mn: $3.42 \times 10^{-7}$, Fe: $3.24 \times 10^{-5}$, Co: $8.32 \times 10^{-8}$, Ni: $1.76 \times 10^{-6}$, Cu: $1.87 \times 10^{-8}$, and Zn: $4.52 \times 10^{-8}$.

For the dusty models, Orion-type graphite and silicate grains (Baldwin et al. 1991; Bergmann & Pastoriza 1989, 1990; Kinney et al. 1991; see also Ho, Shields, & Filippenko 1993). Since forbidden lines arise most effectively in gas clouds with a density near their critical densities, the gas density of the [Fe vii] $\lambda 6087$ and the [Ne v] $\lambda 3426$ emitting regions are expected to be a few times $10^{17}$ cm$^{-3}$. We thus perform model runs with $n_H = 10^{6.5}$, $10^{7.0}$, and $10^{7.5}$ cm$^{-3}$. As for the ionization parameter, we investigate models with $U = 10^{-2.5}$, $10^{-2.0}$, and $10^{-1.5}$, although the ionization parameter of HINERs is thought to be rather high, that is to say, $U \gtrsim 10^{-2}$ (e.g., Murayama & Taniguchi 1999b; Nagao et al. 2001b).

4. PHOTOIONIZATION MODEL CALCULATIONS

To examine whether or not the HINERs are dusty, we investigate how the emission-line flux ratio of [Fe vii] $\lambda 6087$/[Ne v] $\lambda 3426$ depends on certain physical properties by performing calculations of photoionization models with and without dust grains. Our method and the results of the photoionization model calculations are presented below.

4.1. Method

We carry out several photoionization model calculations by using the publicly available code CLOUDY (version 94.00; Ferland 1997, 2000). Here we assume uniform density gas clouds, with a plane-parallel geometry. The parameters for the calculations are (1) the spectral energy distribution (SED) of the input continuum radiation; (2) the hydrogen density of a cloud ($n_H$); (3) the ionization parameter ($U$), i.e., the ratio of the ionizing photon density to the hydrogen density at the irradiated surface of a cloud; (4) the column density of a cloud ($N_H$); and (5) the elemental composition and the dust abundance of the gas.

We adopt the SED in the form of $f_\nu \propto \nu^\alpha$ with $\alpha = 2.5$ for $\lambda > 10 \mu m$, $\alpha = -1.5$ between 10 $\mu m$ and 50 keV, and $\alpha = -2.0$ for $h\nu > 50$ keV, taking account of the SEDs actually observed in AGNs (e.g., Kosi 1978; Storch-Bergman & Pastoriza 1989, 1990; Kinney et al. 1991; see also Ho, Shields, & Filippenko 1993). Since forbidden lines arise most effectively in gas clouds with a density near their critical densities, the gas density of the [Fe vii] $\lambda 6087$ and the [Ne v] $\lambda 3426$ emitting regions are expected to be a few times $10^{17}$ cm$^{-3}$. We thus perform model runs with $n_H = 10^{6.5}$, $10^{7.0}$, and $10^{7.5}$ cm$^{-3}$. As for the ionization parameter, we investigate models with $U = 10^{-2.5}$, $10^{-2.0}$, and $10^{-1.5}$, although the ionization parameter of HINERs is thought to be rather high, that is to say, $U \gtrsim 10^{-2}$ (e.g., Murayama & Taniguchi 1999b; Nagao et al. 2001b).

For the dust-free models we set the gas-phase elemental abundances to be the solar ones, taken from Grevesse & Anders (1989) with extensions by Grevesse & Noels (1993). The adopted gas-phase elemental abundances are as follows: H: 1.00, He: $1.00 \times 10^{-6}$, Li: $2.04 \times 10^{-9}$, Be: $2.63 \times 10^{-11}$, B: $7.59 \times 10^{-10}$, C: $3.55 \times 10^{-4}$, N: $9.33 \times 10^{-5}$, O: $7.41 \times 10^{-4}$, F: $3.02 \times 10^{-8}$, Ne: $1.17 \times 10^{-4}$, Na: $2.06 \times 10^{-6}$, Mg: $3.80 \times 10^{-5}$, Al: $2.95 \times 10^{-6}$, Si: $3.55 \times 10^{-5}$, P: $3.73 \times 10^{-7}$, S: $1.62 \times 10^{-5}$, Cl: $1.88 \times 10^{-7}$, Ar: $3.98 \times 10^{-6}$, K: $1.35 \times 10^{-7}$, Ca: $2.29 \times 10^{-6}$, Sc: $1.58 \times 10^{-7}$, Ti: $1.10 \times 10^{-7}$, V: $1.05 \times 10^{-8}$, Cr: $4.84 \times 10^{-7}$, Mn: $3.42 \times 10^{-7}$, Fe: $3.24 \times 10^{-5}$, Co: $8.32 \times 10^{-8}$, Ni: $1.76 \times 10^{-6}$, Cu: $1.87 \times 10^{-8}$, and Zn: $4.52 \times 10^{-8}$.

For the dusty models, Orion-type graphite and silicate grains (Baldwin et al. 1991; see also Ho, Shields, & Filippenko 1993). Since forbidden lines arise most effectively in gas clouds with a density near their critical densities, the gas density of the [Fe vii] $\lambda 6087$ and the [Ne v] $\lambda 3426$ emitting regions are expected to be a few times $10^{17}$ cm$^{-3}$. We thus perform model runs with $n_H = 10^{6.5}$, $10^{7.0}$, and $10^{7.5}$ cm$^{-3}$. As for the ionization parameter, we investigate models with $U = 10^{-2.5}$, $10^{-2.0}$, and $10^{-1.5}$, although the ionization parameter of HINERs is thought to be rather high, that is to say, $U \gtrsim 10^{-2}$ (e.g., Murayama & Taniguchi 1999b; Nagao et al. 2001b).

4.2. Results of the Model Calculations

In Figure 3 we show the dependences of the flux ratio of [Fe vii] $\lambda 6087$/[Ne v] $\lambda 3426$ on the hydrogen density, the column density, and the ionization parameters of a cloud, and on the presence of dust grains, which are calculated by our photoionization models with and without dust grains. The most striking dependence is that on the presence of dust grains. The models without dust grains predict larger ratios.
of [Fe v]λ6087/[Ne v]λ3426 by a factor of ~10 than the models with dust grains. This factor corresponds to the depletion factor of iron. This implies that the difference in the flux ratio between the models with and without grains is mainly due to the depletion of iron onto dust grains; i.e., the effects of grains on the thermal equilibrium and on the radiation transfer are negligibly small. Indeed, the models without dust grains, but with gas-phase elemental abundances of the dusty model, predict nearly the same flux ratios as those of the dusty models. This also suggests that the iron depletion is the main reason for the difference in the flux ratio of [Fe v]λ6087/[Ne v]λ3426 between the models with and without dust grains.

The remaining dependences of the flux ratio are not so large. As presented in Figure 3, the flux ratio of [Fe v]λ6087/[Ne v]λ3426 is almost independent of the hydrogen density in the range of $10^{6.5}$ cm$^{-3}$ ≤ $10^{7.5}$ cm$^{-3}$, while it depends on the hydrogen column density and the ionization parameter. Note that the models with $U = 10^{-2.5}$ are implausible for gas clouds in HINERs, since those models predict significantly smaller ratios of [Fe v]λ6087/[O iii]λ$\lambda$5007 and [Ne v]λ$\lambda$3426/[O iii]λ$\lambda$5007 (<0.01 and <0.1, respectively) than the observed values (see, e.g., Murayama & Taniguchi 1998a; Nagao et al. 2000b, 2001b). Thus, the dependence of the flux ratio of [Fe v]λ6087/[Ne v]λ3426 on the hydrogen column density and the ionization parameter in the ranges of $10^{20.0}$ cm$^{-2}$ ≤ $N_H$ ≤ $10^{22.0}$ cm$^{-2}$ and $10^{-2.0}$ ≤ $U$ ≤ $10^{-1.5}$ is not so large, i.e., a factor of 2–5. This is consistent with the remark by Ferguson et al. (1997b), and thus determining the exact gas-phase iron abundance by simply using the flux ratio of [Fe v]λ6087/[Ne v]λ3426 appears to be difficult. This is more clearly shown in

**Fig. 1.**—Frequency distributions of the two emission-line flux ratios [Ne v]λ3426/[O iii]λ5007 and [Fe v]λ6087/[O iii]λ5007 for the type 1 AGNs and the type 2 AGNs in our sample.
Figure 4, in which the volume emissivities of the [Fe vii] $\lambda 6087$/[Ne v] $\lambda 3426$ emission are plotted as functions of the depth into the nebula for the models with $n_H = 10^{7.0}$ cm$^{-3}$, with $U = 10^{-2.5}, 10^{-2.0}, 10^{-1.5}$, and with/without dust grains. The ratio of the emissivities for the two emission lines apparently depends on the ionization parameter.

Although the flux ratio of [Fe vii] $\lambda 6087$/[Ne v] $\lambda 3426$ is inappropriate for the exact determination of the gas-phase iron abundance, it can be used to discuss the dust abundances in HINERs. This is because the ranges of the predicted ratio of [Fe vii] $\lambda 6087$/[Ne v] $\lambda 3426$ are well separated between the models with and without dust grains. The dust-free models predict $0.05 \leq F([\text{Fe vii}] \lambda 6087) / F([\text{Ne v}] \lambda 3426) \leq 0.3$, while the dusty models predict $0.007 \leq F([\text{Fe vii}] \lambda 6087) / F([\text{Ne v}] \lambda 3426) \leq 0.04$. Here we should recall that the models with $U = 10^{-2.5}$ are not taken into account since they are not plausible models for clouds in HINERs. Using this flux ratio, we discuss the dust abundances at HINERs in the next section.
5. DISCUSSION

Now we discuss our main problem: are HINERs dusty or not? The predicted range of the flux ratio of [Fe VII] $\lambda6087$/[Ne V] $\lambda3426$ by both the dust-free and the dusty models is smaller than the observed range. This is because the collected data are not corrected for the extinction. Since a wavelength difference between the two emission lines [Fe VII] $\lambda6087$ and [Ne V] $\lambda3426$ is large, the effects of extinction correction are not negligible. Adopting the extinction curve described by Cardelli, Clayton, & Mathis (1989) and $R_V = A_V/E(B-V) = 3.1$, the correction factor for the dust extinction is 1.94 in the case of $A_V = 1$ mag. Therefore, the predicted ranges of the flux ratio of [Fe VII] $\lambda6087$/[Ne V] $\lambda3426$, when the extinction correction of 0 mag $\leq A_V \leq 1$ mag is taken into account, are 0.05 $\leq F([\text{Fe VII}] \lambda6087)/F([\text{Ne V}] \lambda3426) \leq 0.6$ and 0.007 $\leq F([\text{Fe VII}] \lambda6087)/F([\text{Ne V}] \lambda3426) \leq 0.08$ for the dust-free models and the dusty models, respectively. Note that the observed Balmer decrements suggest the reddening amount of 0 mag $\leq A_V \leq 1$ mag for type 1 AGNs (e.g., Cohen 1983; Murayama 1995; Rodriguez-Ardila, Pastoriza, & Donzelli 2000). The range of the flux ratio predicted by the dust-free models is roughly consistent with the observed data, while that predicted by the dusty models is far smaller than the observed data.

To explain the observed range of the flux ratio of [Fe VII] $\lambda6087$/[Ne V] $\lambda3426$ by the dusty models, dust extinction of 3 mag $\leq A_V \leq 10$ mag is required. This required range of the dust extinction is far larger than that estimated from the observed Balmer decrements. This discrepancy may be more significant if the iron depletion factor is smaller than the value we adopt here ($= 0.1$). In cold ISM the iron depletion factor reaches down to 0.01 (e.g., Jenkins, Savage, & Spitzer 1986; Cowie & Songaila 1986). Although this large discrepancy might be explained by introducing dust grains located in/around HINERs selectively, this idea has the following two serious problems. First, to assume the existence of additional dust grains in the inner part of NLRs may conflict with the idea that it is relatively difficult for the dust grains to survive under high photoionizing flux, although we cannot exclude the possibility that the grains could survive under high flux in some situations. We should recall the histograms presented in Figure 1, which suggest that the HINERs are located in the innermost region in NLRs. Second, the inferred amount of extinction, 3 mag $\leq A_V \leq 10$ mag, corresponds to $(N_H) \sim (5-15) \times 10^{21}$ cm$^{-2}$. This is far larger than the column density toward the nuclei of type 1 AGNs derived from X-ray spectral analysis $(N_H) \sim 10^{21}$ cm$^{-2}$; e.g., Reynolds 1997, Leighly 1999). These considerations suggest that it is hard to explain the observed data with the dusty models, even if a very large amount of dust selectively shielding only the HINERs is introduced. Therefore, we conclude that the iron in the HINERs is not significantly depleted onto dust grains. This conclusion is consistent with the idea that HINERs are located at the innermost of NLRs and thus are hidden by dusty tori when seen from a edge-on view toward dusty tori, which is implied by the histograms presented in Figure 1 (see also Pier & Voit 1995; Murayama & Taniguchi 1998a, 1998b; Barth et al. 1999; Tran et al. 2000; Nagao et al. 2000a, 2000b, 2001a, 2001b). Considering that the HINERs are located closer than the dust-sublimation radius (i.e., inner radius of dusty tori), we can understand the absence of internal dust grains in HINERs and the AGN-type dependence of the visibility of high-ionization emission lines, as presented in Figure 1, simultaneously.

Finally, we mention the possible difference in the flux ratio of [Fe VII] $\lambda6087$/[Ne V] $\lambda3426$ between type 1 and type 2 AGNs. Although the difference is not significant, as presented in Figure 2, the difference in the extinction-corrected flux ratio may be larger than that in the observed flux ratio, since the dust extinction is larger on average in type 2 than type 1 AGNs (e.g., Dahari & De Robertis 1988). This difference may suggest that iron in spatially extended HINERs is depleted onto dust grains. Such spatially extended HINERs have been predicted theoretically (e.g., Korista & Ferland 1989; Ferguson et al. 1997b), but the emissivities of high-ionization emission lines at the extended HINERs are expected to be low. Indeed, such extended HINERs are observationally detected only in few Seyfert galaxies (e.g., Golev et al. 1995; Murayama et al. 1998; Nagao et al. 2000a; Nelson et al. 2000; Kraemer & Crenshaw 2000). Therefore, the effect of the presence of the spatially extended HINERs on the observed flux ratios of
[Fe VII] $\lambda 6087$/[Ne v] $\lambda 3426$ seems to be low. However, as suggested by the histograms presented in Figure 1, the innermost region in NLRs, where strong [Fe VII] $\lambda 6087$ and [Ne v] $\lambda 3426$ arise, is hidden for type 2 AGNs. In this case the effect of dusty and spatially extended HINERs may emerge in the observed flux ratios of [Fe VII] $\lambda 6087$/[Ne v] $\lambda 3426$. This idea is a highly speculative one, since the observed difference in the flux ratio of [Fe VII] $\lambda 6087$/[Ne v] $\lambda 3426$ between the type 1 and the type 2 AGNs is marginal. In order to examine this idea observationally, spatial distributions of the flux ratio of [Fe VII] $\lambda 6087$/[Ne v] $\lambda 3426$ should be investigated. Such studies can make it clear how the iron depletion onto dust grains depends on the location in NLRs.

6. CONCLUDING REMARKS

In this paper we have compared the observed data on two high-ionization forbidden emission lines, [Fe VII] $\lambda 6087$ and [Ne v] $\lambda 3426$, with the results of photoionization model calculations and found that the HINERs in NLRs of AGNs are not dusty. This finding was already noted by, e.g.,

Nussbaumer & Osterbrock (1970) and Ferguson et al. (1997b). However, our finding is important because we have shown the absence of dust grains in HINERs for a large sample of AGNs for the first time.

To examine this conclusion more directly, we should carry out spatially resolved imaging observation of the thermal emission of dust in NLRs of AGNs. By using the Atacama Large Millimeter Array (ALMA), we can resolve structures in the 0.01 pc scale by submillimetric imaging observation. This corresponds to D = 3.8 Mpc; Freeman et al. (1977). Thanks to the high spatial resolution it is possible to achieve, we will be able to investigate the distribution of dust in NLRs directly.
