(July 15, 1998)

We consider the p-spin spherical spin-glass model in the presence of an external magnetic field as a general example of a mean-field system where a one step replica symmetry breaking (1-RSB) occurs. In this context we compute the complexity of the Thouless-Anderson-Palmer states, performing a quenched computation. We find what is the general connection between this method and the standard static 1-RSB one, formulating a clear mapping between the parameters used in the two different calculations. We also perform a dynamical analysis of the model, by which we confirm the validity of our results.

I. INTRODUCTION

Two different sets of results can be obtained when studying a statistical model. The first set is given by a static (thermodynamical) analysis of the system, while the second one is obtained from a dynamical approach (eg., Langevin dynamics). In the case of disordered models as spin-glasses, these two sets of results are not in general connected in a straightforward way. The reason for this is that disordered models always exhibit an out of equilibrium dynamical behavior, which is believed to be related to the presence of many metastable states.

However, there is a striking correspondence between certain types of dynamical scenarios and their specific static counterparts. In other words, some particular dynamical results are always associated with the same set of static results and vice-versa. For instance, in the context of the static replica symmetry breaking (RSB) scheme for mean-field spin glasses, we always find a dynamical asymptotic energy larger than the static one in models which are solved by a one step solution (1-RSB), while the two energies are the same in models statically solved by a full RSB solution. This fact suggests that there must be some kind of underlying general physical explanation for these connections.

There is a third method which can be used in the study of disordered systems, which has the advantage to catch some of the results both of the statics and of the dynamics. This method is purely entropic, that is it just deals with the number of states of the system, disregarding their thermodynamical Boltzmann weights. In this context, one simply computes the number of local minima of some mean-field free energy, function of the local magnetizations of the system, and obtains in this way the spectrum of the states as a function of their free energy density. This approach gives information both on the statics and the dynamics of the system since it deals with the whole underlying free energy landscape. We believe that in this context it should be possible to find an explanation for the relation we stated above between statics and dynamics.

As a first step in this direction it is necessary to understand how general and feasible this entropic approach is. Up to now it has given correct results only in one specific mean-field model with 1-RSB solution, the p-spin spherical spin-glass in zero magnetic field. In this model there is a band of free energy densities where the number of states is exponentially large in the size of the system. It has been found that the static and the dynamic free energies (the last being defined as the free energy of the states reached by the dynamics) are equal to the lowest and highest edges of this band, respectively. We believe this to be true in any 1-RSB model. Yet, in order to find out how general this result is, it is not sufficient to consider the p-spin model in zero field. Indeed, due to the absence of the field, this model has some particular features, which make it a special case in the 1-RSB class. It is homogeneous and therefore presents no chaoticity of the states with respect to the temperature. The static and dynamical transitions are both discontinuous, which is not a general property of 1-RSB models. Finally, the dynamical off-equilibrium behavior of the p-spin model with zero field turns out to be much simpler than in the general case. However, this model can be easily generalized by the introduction of an external magnetic field. It then becomes a very general paradigm of 1-RSB models, since as a function of temperature and field it displays all the possible characteristics of these systems.

In the present paper we extend the entropic calculation mentioned above to the p-spin spherical model in presence of a field. In this context we are able to state in the most general way which are the connections with the standard static and dynamical approaches. In particular, we find a one to one mapping between the 1-RSB static parameters and the ones of the entropic calculation, giving a physical interpretation of this relation, until now rather unclear.
The paper is organized in the following way. In Section II we define the model and compute the average logarithm of the number of states, known as complexity. In the next Section we discuss the results and find the relation with the static 1-RSB calculation. In Section III we study the behavior of the complexity as a function of temperature and magnetic field. In Section IV we perform a dynamical analysis of the model and compare it with the results coming from the complexity. Finally, we state our conclusions in Section VI.

II. MODEL AND COMPLEXITY

The $p$-spin spherical model is defined by the Hamiltonian,

$$H(s) = - \sum_{i_1 < \ldots < i_p} J_{i_1 \ldots i_p} s_{i_1} \ldots s_{i_p} - h \sum_i s_i.$$  \hfill (1)

The couplings $J$ are Gaussian variables with zero mean and variance $p! / 2N^{p-1}$ and $h$ is an external magnetic field [10,11,2]. In the context of the Thouless-Anderson-Palmer (TAP) approach [7], it is possible to formulate a set of mean field equations for the local magnetizations $m_i = \langle s_i \rangle$. A mean-field free energy density $f_{\text{TAP}}$, function of the magnetizations $m_i$, was introduced for this model in [8],

$$f_{\text{TAP}} = - \frac{1}{N} \sum_{i_1 < \ldots < i_p} J_{i_1 \ldots i_p} m_{i_1} \ldots m_{i_p} - h \sum_i m_i - \frac{1}{2\beta} \log (1 - q) + g(q),$$  \hfill (2)

where $q = N^{-1} \sum_i m_i^2$ is the self-overlap related to the magnetization $m$ and $g(q) = - \frac{q}{4} \left( (p - 1)q^p - pq^{p-1} + 1 \right)$ is the Onsager reaction term (for a derivation of the TAP free energy see also [12,8]). The minimization of (2) with respect to the $\{m_i\}$ gives the TAP equations of the system,

$$T_k(m) \equiv -p \sum_{i_2 < \ldots < i_p} J_{i_2 \ldots i_p} m_{i_2} \ldots m_{i_p} - h + 2m_k \left( \frac{1}{2\beta (1 - q)} + g'(q) \right) = 0. \hfill (3)$$

In the low temperature phase these equations admit many possible solutions, corresponding to different stationary points of the mean field free energy (2). The minima among all the stationary points can be identified with stable and metastable states of the system.

The complexity $\Sigma(f)$ is defined in the following way,

$$\Sigma(f) \equiv \lim_{N \to \infty} \frac{1}{N} \frac{1}{\log N(f)},$$  \hfill (4)

where $N(f)$ is the number of local minima of the free energy (2), that is, the number of states of the system with free energy density $f$. We average the logarithm of $N$ since we expect this to be the extensive quantity. In order to perform this average it is necessary to introduce replicas. However, when the external field $h$ is set equal to zero, the correct ansatz for the overlap matrix turns out to be symmetric and diagonal. This is equivalent to averaging directly the number $\mathcal{N}$ of solutions (annealed average) [2]. The physical reason for this is that when $h = 0$ there is no preferred direction in the phase space sphere, thus the typical states are orthogonal to each other and their mutual overlap is zero. On the other hand, when $h \neq 0$ there is a migration of the states towards the direction of the magnetic field and the states overlap is different from zero. In this case the quenched average has to be performed. Anyhow, as it is shown below, due to the particular nature of the calculation, the correct ansatz for the overlap matrix is simpler than the 1-RSB used in the statics [2].

In order to compute $\Sigma$ we use the replica trick,

$$\log \mathcal{N} = \lim_{n \to 0} \frac{1}{n} \log \prod_{a=1}^{n} \mathcal{N}^a,$$  \hfill (5)

where each $\mathcal{N}^a$ is given by

$$\mathcal{N}^a(f) = \int Dm^a \prod_{k=1}^{N} \delta \left( T_k(m^a) \right) |\det A(m^a)| \delta \left( f_{\text{TAP}}(m^a) - f \right),$$  \hfill (6)
and \( A_{kl}(m) = \partial_k \partial_l f_{\text{TAP}}(m) \) is the Hessian of the TAP free energy evaluated in a particular solution \( m \). In what follows the symbol \( Dx \) refers to the integration over all the site variables, \( Dx = dx_1 \ldots dx_N \). Let us introduce the following Grassmann representation for the determinant,

\[
\det A(m^a) = \int D\bar{\psi}D\psi \exp \left[ -\bar{\psi}^a A(m^a)\psi^a \right],
\]

and a bosonic representation for the delta functions,

\[
\prod_{k=1}^{N} \delta(T_k(m^a)) = \int D\lambda^a \exp(-\lambda^a T(m^a)),
\]

\[
\delta(f_{\text{TAP}}(m^a) - f) = \int d\omega^a \exp \left[ -\omega^a (f_{\text{TAP}}(m^a) - f) \right],
\]

where the integrals over the variables \( \lambda \) and \( \omega \) are on the imaginary axis. The sums over site indices are always understood whenever site dependent quantities are mutually multiplied. In the rest of the calculation we shall disregard the modulus of the determinant in (8). This approximation is safe for zero magnetic field, as long as we are counting stationary points with a given fixed free energy density (13). Indeed, it can be shown that in this way only the minima of \( f_{\text{TAP}} \) are actually taken into consideration (13). We assume this to hold also with \( h \neq 0 \). We then have,

\[
\Sigma(f) = \lim_{n \to 0} \frac{1}{n N} \log \int Dm D\lambda D\bar{\psi} D\psi d\omega \exp \left[ -S_J(m, \lambda, \psi, \bar{\psi}, \omega) \right],
\]

where the action \( S_J \) is given by

\[
S_J = \sum_{a=1}^{n} \left[ \lambda^a T(m^a) + \bar{\psi}^a A(m^a)\psi^a + N\omega^a (f_{\text{TAP}}(m^a) - f) \right].
\]

The average over the disorder generates couplings between variables with different replica indices. It is convenient to express these terms by means of the following overlap matrices, which can be introduced in the usual way (2,8,13),

\[
NS_{ab} = m^a m^b, \quad NL_{ab} = \lambda^a \lambda^b, \quad NR_{ab} = m^a \lambda^b, \quad NT_{ab} = -\bar{\psi}^a \psi^b.
\]

In terms of the overlap matrices (13) we have,

\[
\Sigma(f) = \lim_{n \to 0} \frac{1}{n N} \log \int DSDLDRTD d\omega \exp \left[ -NS(S, L, R, T, \omega) \right],
\]

where the effective action is given by

\[
-S = \frac{p}{4} \sum_{ab} L_{ab} S_{ab}^{p-1} + \frac{p(p-1)}{4} \sum_{ab} (R_{ab}^2 - T_{ab}^2) S_{ab}^{p-2} + \frac{h^2}{2} \sum_{ab} L_{ab} + \sum_a 2 \left[ g'(S_{aa}) + \frac{1}{2\beta(1 - S_{aa})} \right] (T_{aa} - R_{aa}) - \log \det T + \frac{1}{2} \log \det S + \frac{1}{2} \log \det (R^T S^{-1} R - L) + \frac{p}{2} \sum_{ab} R_{ab} S_{ab}^{p-1} + h^2 \omega \sum_{ab} R_{ab} + nf \omega - \omega \sum_a \left[ g(S_{aa}) - \frac{1}{2\beta} \log(1 - S_{aa}) \right] + \frac{1}{4} \sum_{ab} S_{ab}^2 + \frac{h^2}{2} \omega^2 \sum_{ab} S_{ab}.
\]

We have assumed \( \omega_a = \omega \) since it depends only on one replica index. As usual, we compute the integral (13) by means of a saddle point approximation, so that,

\[
\Sigma(f) = \lim_{n \to 0} \frac{1}{n} \text{Ext}_\phi \left[ -S(f, \phi) \right],
\]

where \( \phi \) stands for all the variational parameters, \( S, L, R, T \) and \( \omega \).

In order to simplify the saddle point equations for the overlap matrices we make use of the fact that action (11) is invariant under the following Becchi-Rouet-Stora-Tyutin (BRST) transformation (14,16).
\[ m_i^a \rightarrow m_i^a + \epsilon \psi_i^a, \quad \psi_i^a \rightarrow \psi_i^a - \epsilon \lambda_i^a, \quad \lambda_i^a \rightarrow \lambda_i^a - \omega^a \epsilon \psi_i^a, \quad \psi_i^a \rightarrow \psi_i^a, \quad \omega^a \rightarrow \omega^a \]  \hspace{1cm} (16)

where \( \epsilon \) is a constant Grassmann parameter. As a consequence, for each operator \( O \), which is a function of the variables \( m^a, \lambda^a, \psi^a, \psi^a \) and \( \omega^a \), we have that \( \langle \delta O \rangle = 0 \), where \( \delta O \) is the variation of \( O \) under (16), and the brackets indicate an average over the measure defined by the action \( S_f \). If we consider the two cases \( O = m^a \psi^a \) and \( O = \lambda^b \psi^a \), we immediately get the equations \( \langle \psi^a \psi^b \rangle = -m^b \lambda^a \) and \( \langle \omega^a \psi^b \rangle = \langle \lambda^b \lambda^a \rangle \). From the definitions (12) we then obtain the following relations for the saddle point values of the overlap matrices,

\[ R_{ab} = T_{ab}, \quad L_{ab} = -\omega T_{ab} \]  \hspace{1cm} (17)

which simplify a lot the calculation. At this point we have to choose an ansatz for the overlap matrices in order to solve the saddle point equations. Let us consider first of all the matrix \( S \), which has an explicit physical meaning. From the definition (12) we see that the diagonal element \( S_{aa} \) corresponds to the self-overlap of an individual TAP solution. On the other hand the off-diagonal elements \( S_{ab} \) correspond to mutual overlaps between different TAP solutions. Given this we assume for the matrix \( S \) the simplest form consistent with this interpretation, that is a symmetric matrix,

\[ S_{ab} = (s_1 - s_0) \delta_{ab} + s_0. \]  \hspace{1cm} (18)

In the saddle point, \( s_1 \) and \( s_0 \) represent respectively the self-overlap and the mutual overlap of the states with free energy density \( f \). As discussed above, in absence of the magnetic field \( s_0 \) vanishes, the matrix \( S \) is diagonal and the quenched average coincides with the annealed one. On the other hand in the presence of the field we expect a value \( s_0 \neq 0 \). Consistently with the ansatz used for \( S \) we set,

\[ T_{ab} = (t_1 - t_0) \delta_{ab} + t_0. \]  \hspace{1cm} (19)

Using the BRST relations (17) and the above form for the matrices \( S \) and \( T \), we can reduce the saddle point equations to the following five coupled equations,

\[
\begin{align*}
0 &= -\omega \left( \frac{p}{2} s_1^{p-1} + \omega^2 \right) - \frac{p(p-1)}{2} t_1 s_1^{p-2} - \frac{1}{z^2} (\omega s_0 + t_0) + 2g'(s_1) + \frac{1}{\beta(1-s_1)}, \\
0 &= \omega \left( \frac{p}{2} s_0^{p-1} + h^2 \right) + \frac{p(p-1)}{2} t_0 s_0^{p-2} - \frac{1}{z^2} (\omega s_0 + t_0), \\
0 &= -\omega \left( \frac{p}{2} s_1^{p-1} + h^2 \right) + \frac{1}{t_1 - t_0} - \frac{t_0}{(t_1 - t_0)^2} - \frac{1}{z^2} (\omega s_0 + t_0), \\
0 &= \omega \left( \frac{p}{2} s_0^{p-1} + h^2 \right) + \frac{t_0}{(t_1 - t_0)^2} - \frac{1}{z^2} (\omega s_0 + t_0), \\
0 &= \frac{p}{4} \left( (t_1 s_1^{p-1} - t_0 s_0^{p-1}) + \omega \left( \frac{1}{2} (s_1^{p-1} - s_0^{p-1}) + h^2 (s_1 - s_0) \right) \right), \\
& \hspace{1cm} - \frac{s_1}{2z} + \frac{\omega s_0 + t_0}{2z^2} (s_1 - s_0) + f - g(s_1) + \frac{1}{2} \log(1-s_1),
\end{align*}
\]  \hspace{1cm} (20)

where \( z = [\omega(s_1 - s_0) + t_1 - t_0] \) and \( g(s) \) is the Onsager term of (3). It is easy to verify that for \( h = 0 \) these equations give the standard result of (8).

### III. CONNECTION WITH THE STATICS

We are now in the condition to compute the complexity \( \Sigma \) in every point of the plane \((T, h)\) and in particular in the regime where the statics of the model display a 1-RSB solution (low temperatures and fields) (8). As we will show below, our results clarify the relation between the present entropic approach and the usual static one. First we note that equations (21) give, after some algebra, the relations,

\[ t_0 = 0, \quad t_1 = \beta(1-s_1). \]  \hspace{1cm} (21)

The physical interpretation of these equations is very simple. The saddle point value of the matrix \( T_{ab} \) is related to the expectation value \( \langle \psi^a \psi^b \rangle \) (see Eq. (13)) and from (7) it is clear that this expectation value is nothing else than the average of the matrix \( A^{-1} \), which is by definition the inverse of the Hessian of the TAP free energy. Therefore,
the parameter $t_1$ can be interpreted as the inverse curvature of the free energy in a typical state with free energy $f$. On the other hand, since $s_1$ is the self-overlap of this state, $\beta(1 - s_1)$ is the the magnetic susceptibility $\chi$. In this way equation (21) gives the expected static relation between the fluctuation $t_1$ and the dissipation $\chi$ of an equilibrium system. In other words, the size $\beta x$ of a state has two different contributions, a thermodynamic one proportional to the temperature and a geometric one proportional to the inverse curvature of the mean field free energy. Equation (21) has not been recognized before in the context of this calculation [3], simply because for $h = 0$ the homogeneity of the $p$-spin model permits to compute everything at zero temperature where $s_1 = 1$, so that the above relation remains hidden.

Due to equation (21) we are left with only three parameters, $s_1, s_0$ and $\omega$. As we have seen, the physical interpretation of $s_1$ and $s_0$ is straightforward, while this is still not the case for $\omega$. In order to better understand what is the role of $\omega$ we note that in the saddle point we have (see equations (13) and (14)),

$$\frac{d\Sigma(f)}{df} = \omega(f).$$

(22)

If we call $f_0$ the ground state free energy, defined by $\Sigma(f_0) = 0$, the number of states having extensive free energy $N_f = N f_0 + \delta f$, is

$$N(\delta f) \sim e^{\Sigma(f_0)} \delta f = e^{\omega(f_0)} \delta f, \quad \delta f \sim O(1).$$

(23)

This equation shows that $\omega(f_0)$ plays the same role as the static parameter $x$, which represents the breaking point in the 1-RSB scheme [4]. Given this, it is clear that, for each value of $(T, h)$, the 1-RSB computation and the present one must map one into the other with the following rule:

$$f_0 = f_{\text{RSB}} \Rightarrow s_1(f_0) = q_1, \quad s_0(f_0) = q_0, \quad \omega(f_0) = \beta x,$$

(24)

where $f_{\text{RSB}}$ is the static 1-RSB equilibrium free energy and $q_1$, $q_0$ and $x$ are the 1-RSB parameters of the static computation (respectively, self-overlap, overlap and breaking point) [4]. It is possible to verify analytically that the relations (24) are fulfilled by our saddle point equations: the complexity is zero at the static free energy $f_{\text{RSB}}$ and here the equations for the parameters $s_1, s_0$ and $\omega$ reduce exactly to the static equations for $q_1, q_0$ and $\beta x$.

In this way we have shown that, despite the symmetric form of the overlap matrices used in our calculation (see Eqs. (13) and (14)), the complexity describes the statics of the model with the same degree of accuracy as the 1-RSB calculation. This point has been rather mysterious, since it was not evident why the two approaches should give the same results. Now the explanation is clear. At the ground state free energy $f_0$ the two calculations simply write in different ways the same quantities. In the RSB approach the self-overlap $q_1$ of the states is introduced, while for the complexity it is natural to deal with the curvature of the states, because of the presence of the Hessian. Yet, these two quantities are, as we have seen, trivially related. Moreover, the breaking point $x$, which is typical of the RSB calculations, has its counterpart in the parameter $\omega$, which has a very simple interpretation in the context of the complexity, being just the derivative of $\Sigma$ with respect to the free energy. Finally, the overlap matrix in the two cases has a slightly different physical meaning and this is why different ansatz are taken for them: in the RSB approach this matrix refers to the overlap between configurations, while in the present context it refers to overlap between states. Due to this, the present approach has one less step of replica symmetry breaking, compared with the standard static one. Clearly, the price we have to pay for having a symmetric overlap matrix is the knowledge of the explicit form of the TAP free energy. Interestingly enough, the parameter $x$ drops from the symmetric overlap matrix, to reappear in disguise as $\omega$. We believe this scenario to be true in each model exactly solved by a 1-RSB static computation.

We stress that what is stated above only holds for $f = f_0$, where the complexity is zero. On the other hand, increasing $f$ provides information on the whole spectrum of the states.

Finally, we would like to recall a completely different method by which the complexity can be computed [19, 20]. This method, which is perhaps less transparent than the one presented in this paper, relates the complexity $\Sigma(f)$ to the static free energy of $r$ real replicas of the system in the following way: $\Sigma(r) = \beta \omega^2 \frac{\partial F_r}{\partial r}$ and $f(r) = \frac{\partial r F_r}{\partial r}$, where $r F_r$ is the free energy density of the $r$ coupled real replicas in the limit where the coupling goes to zero. To obtain $\Sigma$ it is therefore necessary to compute $F_r$. For systems with 1-RSB one usually assumes a one step of breaking also for the overlap matrix related to $F_r$, with a fixed breaking parameter equal to $r$ and two variational parameters $q_1$ and $q_0$ [19, 21]. In this case the expression of $F_r$ as a function of $q_1, q_0$ and $r$ is analogous to the usual static one, except for the fact that it has to be minimized with respect to $q_0$ and $q_1$, but not with respect to $r$. With these assumptions it is possible to obtain an explicit expression of $\Sigma$ in terms of $f, q_1, q_0$ and $r$, where $q_1$ and $q_0$ are given by their saddle point values, while $r$ is fixed by the above equation for $f(r)$. If we now compare this expression for $\Sigma$ with the one coming from our calculation, we find that they are perfectly consistent: the equations for $q_1, q_0$ and $r$ are exactly the same as the ones for $s_1, s_0$ and $\beta \omega$, and $\Sigma(r)$ coincides with (13).
IV. BEHAVIOR OF THE COMPLEXITY IN THE TEMPERATURE AND FIELD PLANE

From equations (14), (15) and (21) we obtain the explicit expression of the complexity

$$\Sigma(f) = \frac{p}{4} \omega_1 s_1^{p-1} + \frac{h^2}{2} \omega_1 - \frac{1}{2} \log t_1 + \frac{1}{2} \log z + \frac{1}{2} \omega s_0$$

$$+ \omega \left( f - g(s_1) + \frac{1}{2 \beta} \log(1 - s_1) \right) + \frac{\omega^2}{4} (s_1^p - s_0^p) + \frac{h^2}{2} \omega^2 (s_1 - s_0),$$

with $t_1 = \beta(1 - s_1)$ and $s_1, s_0$ and $\omega$ given by the saddle point equations (20).

Let us now analyze the behavior of the complexity in the $(T, h)$ plane. For small enough values of temperature and field many pure states are present, therefore we expect the complexity to be different from zero in a finite range of free energy densities. Actually this is what happens. In Fig. 1 we show $\Sigma(f)$ as a function of $f$ at fixed small values of $T$ and $h$: $\Sigma$ is defined between a minimum free energy density $f_0$ where it is zero, and a threshold free energy density $f_{th}$ where it takes its maximum value. Since for high values of temperature and field only one (finite magnetization) paramagnetic state is present [2], we expect that increasing $T$ and $h$ the number of existing states progressively decreases until one single state is left. Indeed, if we look at $\Sigma(f)$ at a fixed $h$, but at different values of $T$, we find that the interval of free energies $[f_0, f_{th}]$ where $\Sigma$ is defined, becomes smaller and smaller as the temperature is increased, and finally it shrinks to a single point, with $\Sigma = 0$, at a certain critical temperature $T_c(h)$. For $T > T_c(h)$, $\Sigma(f)$ is defined only in one point, where $\Sigma = 0$, and $f$ here coincides with the replica symmetric static free energy, that is, the free energy of the single paramagnetic state. In Fig. 2 the line $T_c(h)$ is shown in the $(T, h)$ plane [22].

This line separates the region of the plane where only one pure state exists ($T > T_c(h)$) from the region where many pure states are present ($T < T_c(h)$) and therefore we identify it as the geometrical transition line. We note that this line is monotonically decreasing with the field, so that there is no ‘re-entrance’ [23]. We find that the geometrical transition line coincides with the line where the RSB static solution ceases to exist [2]. This indicates that, as in the case with $h = 0$ [4], the states with the lowest free energy density are the last to disappear. We note that the critical line $T_c(h)$ does not coincide in the whole plane with the transition line given by the statics (dotted line in Fig. 2) [22]. Indeed the two lines coincide only for $h > h^*$, where the static transition is continuous ($q_1 = q_0$ at the transition), while they are strictly different for $h < h^*$ (discontinuous transition) [2]. This is consistent with the different physical scenarios corresponding to the continuous and the discontinuous transitions. In the first case, the transition corresponds to different states which merge into a unique ergodic component, so above the transition line only one state is present. In the second case, many pure states with finite complexity exist both above and below the transition line, and the transition corresponds to the point where the lowest states ($f = f_0 = f_{RSB}$) become the relevant ones from a thermodynamical point of view [13].

V. THRESHOLD ENERGY AND DYNAMICAL BEHAVIOR

As mentioned in the previous section, at fixed temperature and field, the complexity is defined within a certain range $[f_0, f_{th}]$ of free energy densities. It is well known that at $h = 0$ in the low temperature region the states with $f = f_{th}$ are the dynamically relevant ones, that is, their energy density coincides with the asymptotic value of the dynamical energy [23]. In this section we show that this also holds at non zero values of the field. To check this point we will perform a dynamical analysis of the model with $h \neq 0$ in order to compare the dynamical asymptotic energy with the energy of the threshold states of the complexity. The equivalence between the threshold and dynamical energies can be confirmed numerically for any temperature and field, but for the sake of simplicity we will only quote the analytical results at zero temperature and small field. If we take the limit $T \to 0$ of Eqs. (20) and expand it for small fields we get the following expression for the energy density of the threshold states,

$$E_{th} = - \sqrt{\frac{2(p - 1)}{p}} \left( 1 + \frac{p - 1}{p} h^2 \right) + O(h^3), \quad T \to 0. \quad (26)$$

Let us now compute the asymptotic dynamical energy [3] (for a more complete dynamical analysis in similar cases see [12,23]). The relaxation dynamics for the system is given by the Langevin equations,

$$\dot{s}_i(t) = -\beta \frac{\delta H}{\delta s_i(t)} - y(t)s_i(t) + \nu_i(t), \quad (27)$$
where \( y(t) \) is a Lagrange multiplier which enforces the spherical constraint, and \( \nu_i(t) \) is a Gaussian noise with zero mean and variance 2. The dynamics is completely determined by the equations for the two-time correlation and response functions, \( C(t,t') = \frac{1}{N} \sum_i (s_i(t)s_i(t')) \) and \( G(t,t') = \frac{1}{N} \sum_i \frac{\partial s_i(t)}{\partial \nu_i(t')} \), and for the magnetization \( m(t) = \frac{1}{N} \sum_i s_i(t) \). These equations are [3,24].

\[
\partial_t C(t,t') = -y(t)C(t,t') + \mu \int_0^t dt'' C^{-1}(t,t'')G(t',t'') \tag{28}
\]

\[
\partial_t G(t,t') = -y(t)G(t,t') + \delta(t-t') + \mu(p-1) \int_0^t dt'' G(t,t'')C^{-2}(t',t'')G(t'',t'), \tag{29}
\]

\[
\dot{m}(t) = -y(t)m(t) + \mu(p-1) \int_0^t dt'' G(t,t'')C^{-2}(t',t'')m(t'') + \beta h, \tag{30}
\]

where \( \mu = p \beta^2/2 \). Another equation for \( y(t) \) is obtained self-consistently exploiting the spherical constraint,

\[
y(t) = 1 - p \beta \mathcal{E}(t) - (p-1) \beta h m(t), \tag{31}
\]

where \( \mathcal{E}(t) = N^{-1}(\mathcal{H}(t)) \) is the dynamical energy density. In the limit \( t \to \infty \) we have the following expression for the asymptotic dynamical energy \( \mathcal{E}_\infty = \lim_{t \to \infty} \mathcal{E}(t) \),

\[
\mathcal{E}_\infty = \frac{1 - y_\infty}{p \beta} - \frac{p-1}{p} h m_\infty, \tag{32}
\]

where \( y_\infty \) and \( m_\infty \) are the corresponding asymptotic values for the Lagrange multiplier and the magnetization. In order to compute \( \mathcal{E}_\infty \) we then have to find \( y_\infty \) and \( m_\infty \) by solving asymptotically the set of dynamical equations [23]-[34].

In [3] it has been shown that for large times there are two regimes for the correlation and response functions. The first regime corresponds to time separations \( \tau = (t-t') \) such that \( \tau/t \to 0 \), where the equilibrium fluctuation dissipation theorem (FDT) holds, so that \( G_{\text{FDT}}(\tau) = -\partial_\tau C_{\text{FDT}}(\tau) \). The second regime, known as aging regime, corresponds to \( \tau/t \sim O(1) \). Here time translation invariance is violated and FDT cannot be applied. The response function is related to the correlation function by \( C_{ag}(t,t') = x_d \partial_{t'} C_{ag}(t,t') \), where \( x_d \) parameterizes the violation of FDT. The asymptotic values for the correlation functions in both regimes are,

\[
\lim_{\tau \to \infty} C_{\text{FDT}}(\tau) = \lim_{t'/t \to 1} C_{ag}(t,t') = q, \quad \lim_{t'/t \to 0} C_{ag}(t,t') = q_0. \tag{33}
\]

In the limit \( \tau \to \infty \), the equation for \( C_{\text{FDT}}(\tau) \) yields a relation between \( y_\infty \) and \( q \) which reads,

\[
y_\infty = (1-q)^{-1} + \mu(1-q^{-1}). \tag{34}
\]

If we take the limit \( t'/t \to 1 \) in the equation for \( C_{ag}(t,t') \) we obtain the equation for \( q \),

\[
\mu q^{p-2}(1-q)^2 - (p-1)^{-1} = 0. \tag{35}
\]

It is now clear that neither \( q \) nor \( y_\infty \) depend on the field. Therefore, all the dependence of the energy on the field is given by the second term of Eq. (22), while the first term corresponds to the asymptotic energy in zero field [3].

To obtain the asymptotic magnetization \( m_\infty \) we need to solve the coupled equations for \( m_\infty, q_0 \) and \( x_d \) coming from Eq. (34), and from the limits \( t'/t \to 0 \) and \( t'/t \to 1 \) of the equation for \( C_{ag}(t,t') \),

\[
0 = -y_\infty m_\infty + \mu \left[1 - q^{-p-1}(1-x)\right] m_\infty + \beta h, \tag{36}
\]

\[
0 = -y_\infty q_0 + \mu(1-q)q_0^{p-1} + \mu q_0(1-q^{-p-1}) + \mu x_d(q_p^{-1} - q_0^p) + \beta h m_\infty, \tag{37}
\]

\[
0 = -y_\infty + 1 + \mu(x - 1)q_p^p + \mu(x - 1)x_\infty q_0^p + \beta h m_\infty. \tag{38}
\]

The analytic solution for small \( h \) has a simple form,

\[
m_\infty = (p-1)(1-q) \beta h + O(h^2), \tag{39}
\]

\[
y_0 = O(h^2), \tag{40}
\]

\[
x_d = \frac{(p-2)(1-q)}{q} + O(h^2). \tag{41}
\]
From here we obtain the dynamical energy,

\[ \mathcal{E}_\infty = -\frac{\beta}{2} \left[ 1 - q^p \left( 1 - \frac{(p-2)(1-q)}{q} \right) - \frac{(p-1)^2(1-q)}{p} h^2 + O(h^3) \right]. \tag{42} \]

In the limit \( T \to 0 \) it can be seen from equations (35), (42) and (26) that \( \mathcal{E}_\infty = E_{th} \). As already said, it is possible to check numerically that these two energies are the same in the whole plane \((T, h)\).

VI. CONCLUSIONS

In this paper we have computed the complexity \( \Sigma \) of the states in a very general 1-RSB mean-field model for disordered systems, namely, the \( p \)-spin spherical model in presence of an external magnetic field. We find a region of the \((T, h)\) plane where \( \Sigma \) is a monotonic increasing function of the free energy density \( f \), defined in an interval \([f_0, f_{th}]\). The lower band edge \( f_0 \), defined by \( \Sigma(f_0) = 0 \), is always equal to the free energy density of the static 1-RSB solution, that is, \( f_0 = f_{RSB} \). On the other hand, the threshold value \( f_{th} \) gives the free energy density of the states asymptotically reached by the non-equilibrium dynamical evolution of the system.

Our most important result is the one to one mapping we are able to find between the equations and the parameters of the complexity at \( f = f_0 \) and the ones of the 1-RSB static approach. This shows that the two calculations are essentially the same, even if the ansatz taken for the overlap matrices seem so different in the two cases.

We would like to add some further comments on what is the main interest of the present work. There are different methods by which the complexity of a model can be computed \cite{24,25,19}. The one used in this paper is the most intuitive and transparent, since it simply counts the number of minima of the mean-field free energy function. However, from a technical point of view, this method is far from being straightforward and up to now a clear quenched calculation of the complexity was lacking. Many efforts have been done in this direction for the Sherrington-Kirkpatrick model \cite{3}, which has a full RSB static solution \cite{26,27,21}. However, in that case neither the physical meaning of the adopted ansatz nor the eventual consistency of the lower band edge with the static free energy density were completely satisfying. In the present paper, in the context of a simpler 1-RSB model, we find in a clear way how the computation has to be performed and what is the meaning of the ansatz. Therefore, we now believe to have this method under control.

It would be interesting to use this same method for a deeper analysis of the free energy landscape. Indeed, it is generally believed that in the dynamics of glassy systems a crucial role is played not only by the minima of the Hamiltonian, but also by unstable stationary points \cite{27,13}. In this context, an entropic computation of stationary points of any nature is of primary interest.

FIG. 1. The complexity $\Sigma(f)$ as a function of the free energy density $f$ for $T = 0.2$, $h = 0.2$ and $p = 3$. The minimum value $\Sigma = 0$ occurs at $f_0 = f_{\text{RSB}} = -0.8322$. The maximum value is at $f_{\text{th}} = -0.8213$, which is the free energy density of the states reached by the dynamics.
FIG. 2. The full line corresponds to the critical temperature line $T_c(h)$ where $\Sigma$ reduces to a point and the RSB static solution disappears, for $p = 3$. The dotted line corresponds to the static transition line. The two lines are coincident for fields $h > h^* = 0.408$. The static transition is continous for $h > h^*$, and dicontinous for $h < h^*$. The region C is the region of coexistence of RS and RSB solutions.
