BACKGROUND: Perfluorooctanoic acid (PFOA) is a potent hepatocarcinogen and peroxisome proliferator (PP) in rodents. Humans are not susceptible to peroxisome proliferation and are considered refractory to carcinogenesis by PPs. Previous studies with rainbow trout indicate they are also insensitive to peroxisome proliferation by the PP dehydroepiandrosterone (DHEA), but are still susceptible to enhanced hepatocarcinogenesis after chronic exposure.

OBJECTIVES: In this study, we used trout as a unique in vivo tumor model to study the potential for PFOA carcinogenesis in the absence of peroxisome proliferation compared with the structurally diverse PPs clofibrate (CLOF) and DHEA. Mechanisms of carcinogenesis were identified from hepatic gene expression profiles phenotypically anchored to tumor outcome.

METHODS: We fed aflatoxin B1 or sham-initiated animals 200–1,800 ppm PFOA in the diet for 3 weeks for tumor analysis. We subsequently examined gene expression by cDNA array in animals fed PFOA, DHEA, CLOF, or 5 ppm 17β-estradiol (E2, a known tumor promoter) in the diet for 14 days.

RESULTS: PFOA (1,800 ppm or 50 mg/kg/day) and DHEA treatments resulted in enhanced liver tumor incidence and multiplicity (p < 0.0001), whereas CLOF showed no effect. Carcinogenesis was independent of peroxisome proliferation, measured by lack of peroxisomal β-oxidation and catalase activity. Alternately, both tumor promoters, PFOA and DHEA, resulted in estrogenic gene signatures with strong correlation to E2 by Pearson correlation (R = 0.81 and 0.78, respectively), whereas CLOF regulated no genes in common with E2.

CONCLUSIONS: These data suggest that the tumor-promoting activities of PFOA in trout are due to novel mechanisms involving estrogenic signaling and are independent of peroxisome proliferation.

KEY WORDS: clofibrate, dehydroepiandrosterone, estradiol, hepatocarcinogenesis, microarray, perfluorooctanoic acid, peroxisome proliferation, rainbow trout. Environ Health Perspect 116:1047–1055 (2008). doi:10.1289/ehp.11190 available via http://dx.doi.org/ [Online 9 May 2008]

Perfluorooctanoic acid (PFOA) is a member of a class of perfluorinated compounds that are used widely in consumer products and industrial applications including surfactants, lubricants, textile coatings, food packaging, and flame retardants. PFOA is also a degradation product of other fluoropolymers that is environmentally persistent and accumulates in terrestrial and aquatic biota and in human serum (Calafat et al. 2007; Houde et al. 2006; Prevedouros et al. 2006). Estimation of PFOA half-lives in serum varies broadly, depending on species and sex, and ranges from days in rats (Vanden Heuvel et al. 1991) and cynomolgus monkeys (Butenhoff et al. 2004) to almost 4 years in occupationally exposed humans (Olsen et al. 2007). Although some perfluorinated chemicals have been voluntarily removed from the market by manufacturers over concerns related to environmental occurrence and stability, PFOA is still produced commercially, and its potential risk to humans continues to be evaluated (U.S. Environmental Protection Agency 2006). PFOA is a potent peroxisome proliferator (PP) similar to other perfluorinated chemicals (Sohlenius et al. 1992). Overall, PPs comprise a structurally diverse group of nongenotoxic carcinogens including certain hypolipidemic drugs [clofibrate (CLOF), ciprofibrate], industrial plasticizers (phthalates), herbicides (phenoxyacetic acids), and organic solvents (trichloroethylene). PPs are known to cause hepatomegaly, altered cholesterol homeostasis, increased number and size of peroxisomes, and increased β-oxidation and α-oxidation of fatty acids in peroxisomes and microsomes, respectively, in susceptible animal models (Moody et al. 1991). Prolonged exposure to PPs, including PFOA, also results in increased liver tumor incidence in rodents (Abdellatif et al. 1991). Although the causative link between peroxisome proliferation and hepatocarcinogenesis has not been firmly established, PPs are thought to enhance liver tumors in rodent models as a result of peroxisome proliferation through sustained oxidative stress and regulation of cellular proliferation and differentiation (Reddy and Rao 1989). Many PP-mediated effects occur through ligand-dependent activation of the nuclear receptor, PP-activated receptor alpha (PPARα), and consequently do not occur in PPARα-null mice (Peters et al. 1997). Despite the apparent toxicity of PFOA and other PPs in rodents, humans are relatively insensitive to peroxisome proliferation by this class of compounds (Fruchart et al. 1998). In fact, marked species differences exist in susceptibility to peroxisome proliferation such that rodents are highly sensitive, whereas humans and certain other models, including rainbow trout, guinea pigs, and nonhuman primates, show little to no evidence of peroxisome proliferation (Butenhoff et al. 2002; Lake et al. 1989; Orner et al. 1996). The insensitivity of humans to PP toxicity is attributed to the approximately 10-fold lower expression of PPARα receptor in liver compared with mouse (Palmer et al. 1998). It is generally accepted that humans are likely refractory to hepatocarcinogenesis caused by peroxisome proliferation via a PPARα mode of action; however, there is also accumulating evidence for PFOA toxicity independent of peroxisome proliferation. For example, PFOA induces Leydig-cell and pancreatic acinar-cell tumors in chronic rodent bioassays, similar to some other PPs (Biegel et al. 2001). Leydig-cell tumor formation was correlated with elevated serum estradiol and inhibition of testosterone synthesis rather than peroxisome proliferation in these cells. PFOA was also shown to cause hepatomegaly in PPARα-null mice and cymolougus monkeys without an increase in typical measures of peroxisome proliferation, suggesting that PFOA can cause liver toxicity presumably independent of PPARα, which may be relevant for humans (Butenhoff et al. 2002; Yang et al. 2002). These studies show the potential for significant toxicity by PFOA to occur independent of peroxisome proliferation and indicate that use of PP-insensitive species in...
evaluation of novel PFOA effects may be important for identification of mechanisms that can be extrapolated to humans.

In this study, we examined the in vivo effects of chronic PFOA exposure on hepatocarcinogenesis in rainbow trout, a model used for chemically induced liver cancer in humans for over 40 years (Bailey et al. 1996). PFOA was evaluated as both a complete carcinogen and as a promoter of aflatoxin B1 (AFB1)-induced liver cancer compared with two structurally diverse PPs, CLOF and dehydroepiandrosterone (DHEA). CLOF is a hypolipidemic drug and known PPAR agonist that acts as a complete carcinogen in rodents (Reddy and Qureshi 1979). DHEA, an adrenal steroid in humans, is classified as a PP based on its ability to induce peroxisome proliferation in rodents, but appears to operate independently of PPARs (Webb et al. 2006).

Our laboratory previously demonstrated that rainbow trout are insensitive to peroxisome proliferation by DHEA but are still responsive to induction of liver cancer by this compound (Orner et al. 1995). Rainbow trout are also susceptible to tumor enhancement by pro-oxidants (Kelly et al. 1992), which is a proposed mechanism for PP-induced liver cancer in rodents. The goals of this study were to (a) determine the potential for PFOA-mediated carcinogenesis in vivo in the absence of peroxisome proliferation, (b) investigate whether this mode of action is common across a class of known PPs or PPAR agonists, and (c) identify potential mechanisms of carcinogenesis from phenotypic anchoring of global gene expression profiles to tumor outcome. Toxicogenomic profiling has been successfully used in rainbow trout to examine mechanisms of chemical hepatocarcinogenesis (Tilton et al. 2005, 2006, 2007) and has also been used in other models to determine effects of PFOA in liver (Guruge et al. 2006). Overall, we determined that PFOA can enhance hepatocarcinogenesis postinitiation in the trout model at 1,800 ppm in the diet, or 50 mg/kg/day. However, tumor promotion was not correlated to peroxisome proliferation, but rather to estrogenic signaling in trout liver, which is a novel mechanism of carcinogenicity reported for PFOA in a PP-insensitive species.

Materials and Methods

Materials and animals. Analytical-grade AFB1, 17β-estradiol (E2), and DHEA were purchased from Sigma Chemical Co. (St. Louis, MO). CLOF and PFOA were purchased from Fluka Chemical Corp. (St. Louis, MO). All other compounds were purchased from Sigma Chemical Co. unless otherwise stated. Mt. Shasta strain rainbow trout (Oncorhynchus mykiss) were hatched and reared at the Oregon State University Sinnhuber Aquatic Research Laboratory in 14°C flowing well water on a 12:12 hr light/dark cycle. All animal protocols were performed in accordance with Oregon State University Institutional Animal Care and Use Committee guidelines. Animals were treated humanely and with regard for alleviation of suffering.

Tumor experiment, necropsy, and histopathology. Approximately 1,000 fry were initiated at 10 weeks posthatch with an aqueous exposure to 0.01 ppm AFB, for 30 min. Sham-exposed trout were exposed to vehicle alone (0.01% ethanol) and served as non-initiated controls for each treatment. After initiation, fry were fed Oregon Test Diet (OTD), a semipurified casein-based diet, for 3 months (Lee et al. 1991). Trout were then randomly (within initiator group) divided into experimental treatment groups (140 animals/treatment) and fed experimental diets containing 200 or 1,800 ppm PFOA, 1,800 ppm CLOF, or 1,800 ppm DHEA ad libitum (2.8–5.6% body weight) 5 days/week for 6 months, a protocol similar to that previously described for DHEA (Orner et al. 1995). The PFOA concentrations in the diet for 200 and 1,800 ppm are equivalent to 5 and 50 mg/kg/day, respectively. Diets were prepared monthly and stored frozen at −20°C until 2–4 days prior to feeding, when diets were allowed to thaw at 4°C.

At 9 months postinitiation, juvenile fish were euthanized by deep anesthesia with 250 ppm tricaine methanesulfonate and sampled for liver tumors over a 2-day period. Livers were fixed in Bouin’s solution for 2–7 days for histologic identification and examination of tumors with hematoxylin and eosin. Neoplasms were classified by the criteria of Hendricks et al. (1984). The effect of dietary PPs on tumor incidence was modeled by logistic regression (GENMOD procedure, SAS version 9.1; SAS Institute, Cary, NC). Tumor multiplicity data (number of tumors per tumor-bearing animal) were analyzed by the Kruskal-Wallis test with p-values based on the exact permutation distribution (StatXact, version 2.04; Cytel Software, Corp., Cambridge, MA).

Microarray experiment. Juvenile trout, 12–18 months of age, were maintained in separate 375-L tanks (three tanks) for each treatment, with five fish per tank. Animals were fed a maintenance ration (2.8% wt/wt) of OTD. Administration of experimental diets containing 500 or 1,800 ppm PFOA, 1,800 ppm CLOF, 750 ppm DHEA, 5 ppm E2, or 0.1% dimethyl sulfoxide (DMSO) vehicle control was carried out for 14 days. The concentrations of E2 and DHEA were chosen based on their ability to maximally induce vitellogenin (VTG) and/or act as hepatic tumor promoters in trout (Nunez et al. 1989). On day 15, fish were euthanized by deep anesthesia with 250 ppm tricaine methanesulfonate. Approximately 100 mg liver tissue from individual fish was minced, stored in TRIzol Reagent (Invitrogen, Carlsbad, CA) and quick-frozen in liquid nitrogen for enzyme expression analysis. The rest of the liver was quick-frozen in liquid nitrogen for enzyme assays.

Total hepatic RNA was isolated from individual trout liver using TRIZol Reagent, followed by cleanup with RNeasy Mini Kits (QIAGEN, Valencia, CA) according to manufacturer instructions. Equal amounts of RNA (micrograms) were pooled from each of the five fish per tank (three tanks or biological replicates) for every treatment. RNA was pooled from individual animals to reduce variability across replicates due to individual differences, allowing for analysis of gene expression changes that are representative of the population. A reference sample was created from RNA pooled from 15 vehicle control fish. RNA quality and quantity were assessed by agarose gel electrophoresis, spectrophotometric absorbency at 260/280 nm, and bioanalyzer trace (Bioanalyzer 2100; Agilent, Palo Alto, CA).

Peroxosomal β-oxidation and catalase activity. The β-oxidation of palmitoyl coenzyme A (CoA) was measured by the spectrophotometric method of Mitchell et al. (1985) in peroxisomal fractions prepared by differential centrifugation, as described previously (Orner et al. 1995). Enzyme activity was measured at 340 nm (20°C) and expressed as amount of NAD+ (nicotinamide adenine dinucleotide) reduced per minute per milligram of protein. Catalase activity was measured spectrophotometrically by the decay of hydrogen peroxide, as described previously (Aebi 1984; Orner et al. 1995). Enzyme activity was measured at 240 nm (20°C) and expressed as specific activity (micromoles per minute per milligram of protein). Protein was quantified by the method of Lowry et al. (1951).

Serum VTG and E2. VTG was quantified in trout serum by enzyme-linked immunosorbent assay (ELISA), as previously described (Tilton et al. 2006). Protein concentrations were determined by the method of Lowry et al. (1951). VTG concentrations were determined by optical density on a SpectraMax 190 plate reader (Molecular Devices, Sunnyvale, CA) based on comparison with a trout VTG standard curve with a detection limit for this assay of 6.25 ng/mL. Serum VTG was also measured by Western blot using the same antibody to capture images from representative samples (Oganesian et al. 1999). E2 was quantified in trout serum by enzyme immunosorbent assay according to the manufacturer protocol (Cayman Chemical, Ann Arbor, MI).

Microarray hybridization and analysis. Rainbow trout 70-mer oligonucleotide arrays (OSUrbt, version 2.0) containing 1,672 elements, representing approximately 1,400 genes, were created at Oregon State University.
Microarray construction and quality control have been described previously (Tilton et al. 2005). Hybridizations were performed with the Genisphere Array 350 kit and instructions (Genisphere, Hatfield, PA) using standard reference design with dye swapping as described (Tilton et al. 2007). Data were background-subtracted and normalized by locally weighted scatterplot smoothing (LOWESS), which is recommended for two-color experiments to eliminate dye-related artifacts and produce ratios that are not affected by signal intensity values. Stringent criteria were used to filter for genes that were regulated at least 1.8-fold consistently in all features from biological replicates and had a p-value < 0.05 by Welch’s t-test (GeneSpring version 6; Silicon Genetics, Redwood City, CA). Genes that met these criteria were minimally categorized based on function using Gene Ontology (Gene Ontology Consortium 2008) and OMIM [National Center for Biotechnology Information (NCBI) 2008c] databases for putative homolog descriptions. Hierarchical clustering of gene expression profiles was performed in GeneSpring, and comparisons of microarray and real-time polymerase chain reaction (PCR) gene regulation were performed with GraphPad Prism (GraphPad Software, San Diego, CA).

Real-time quantitative reverse transcription (qRT)-PCR. To assess the authenticity of results from the microarray analyses, we also analyzed mRNAs for select genes using real-time RT-PCR. Total RNA was isolated as described above and was treated with DNase (Invitrogen) according to manufacturer’s protocol. cDNA was synthesized from 2 µg RNA with an oligo (dT)12 primer using SuperScript (Invitrogen) according to manufacturer’s instructions, with a final volume of 100 µl. Synthesized cDNAs (1 µl) were used as templates for amplification of specific gene products in total volumes of 20 µl containing 1X SYBR Green master mix (Invitrogen qPCR kit; Finnzymes, Espoo, Finland) and 0.3 µM of each primer. Primer sequences were as follows: 5’-GAGTGGGGCGAGGTTGG-3’ and 5’-GGTCCCCGTTTGTTAGGT-3’ for cytochrome P450 family 1A (P450); 5´-TGGTGCGGTTTGGTAGGT-3´ for GAPDH (TC47576). PCR was performed using a DNA Engine Cycler and Opticon 2 Detector (MJ Research, Waltham, MA). PCR amplification was quantified (picograms) from the C(T) value based on standard curves to ensure that quantification was maintained within a linear range. Standards were created from gel-purified PCR products (QIAIIX; QIAGEN) for each primer set after quantification with the PicoGreen dsDNA Quantification Kit (Molecular Probes, Eugene, OR) and serial dilutions ranging from 0.25 to 100 ng DNA. All signals were normalized against GAPDH, and ratios were calculated for treated samples compared with control. Because expression of GAPDH was not altered by treatment based on either microarray analysis or RT-PCR, we found it to be an appropriate housekeeping gene for normalization in this study.

Results

Tumor study. Exposure to experimental diets containing 1,800 ppm PFOA (equivalent to 50 mg/kg/day) or DHEA significantly (p < 0.0001) enhanced the incidence of liver tumors in AFB1-initiated trout above control animals (Figure 1). In addition, the multiplicity increased significantly (p < 0.0001) in both PFOA- and DHEA-fed trout (Figure 1A). Some animals fed promotional diets after initiation with AFB1, had more than six tumors per liver, compared with animals on the control diet, most of which had 1–2 tumors per liver (in tumor-bearing animals). In contrast, postinitiation feeding with CLOF resulted in no increase in either tumor incidence or multiplicity. The historical spontaneous liver tumor incidence in 9-month-old trout fed control diet is 0.1%. Consequently, no tumors were observed in noninitiated animals fed control, CLOF, or PFOA diets. However, consumption of 1,800 ppm DHEA in the diet for 6 months resulted in 20% tumor incidence in noninitiated animals, which is consistent with previous observations in our laboratory that DHEA acts as a complete hepatocarcinogen in trout (Table 1) (Orner et al. 1995). Histologic examination of liver tumors confirmed previous findings from our laboratory that mixed carcinoma is the predominant cell type.

Figure 1. Effects of test compounds on tumor incidence, serum VTG, and serum E2 compared with DMSO vehicle control. (A) Tumor incidence and multiplicity after exposure to CLOF, DHEA, or PFOA in the diet for 6 months compared with control (postinitiation by immersion in 10 ppb AFB1 (each treatment consisted of a single tank of 68–100 individuals). (B) Serum VTG in trout after exposure to E2, DHEA, and PFOA in the diet for 5 days as determined by Western blot (representative images shown) and ELISA (n = 4). (C) Serum E2 in trout after exposure to E2, DHEA, and PFOA in the diet for 14 days, as determined by enzyme immunoassorbent assay. For (B) and (C), pools of blood plasma were obtained from five individual males in each replicate tank (n = 3).

**p < 0.01 compared with control with one-way ANOVA with Dunnett’s multiple comparison test. #p < 0.0001 for tumor incidence and *p < 0.0001 for multiplicity compared with control, calculated by logistic regression analysis and Kruskal-Wallis test, respectively.

Table 1. Effects of PPs on tumor type.

*aAnimals were initiated with 10 ppb AFB1, as fry and fed control diet for 3 months, followed by 6-month exposure to control diet, 1,800 ppm CLOF, 1,800 ppm DHEA, or 200 or 1,800 ppm PFOA in the diet postinitiation (promotion). **p < 0.05 compared with control animals (within initiator group) by logistic regression analysis.
Some significant tumor promotion and hepatomegaly in trout liver after PFOA treatment, both of which are characteristic of PPs, typical enzymatic measurements of liver peroxisomal activity were not elevated by PFOA. Analysis of hepatic peroxisomal palmitoyl CoA oxidase activity in trout fed PPs for 6 months provided no evidence that CLOF, DHEA, or PFOA induced peroxisome enzymatic activities (Table 2). In fact, significant reduction in β-oxidation was observed for 1,800 ppm PFOA and DHEA (p < 0.01). Similarly, β-oxidation and catalase activity were not increased in liver peroxisomes and liver homogenates of animals from the microarray experiment after 14-day exposure to experimental diets (Table 2). Ultrastructural examination of treated livers revealed no evidence of increased size or number of peroxisomes (data not shown). Because DHEA was previously found to induce hepatic VTG, a glucolipoprotein egg yolk precursor produced in response to estrogen (Orner et al. 1996), animals exposed to PFOA were examined for induction of this estrogenic marker. VTG was subsequently detected in the serum of animals treated with 1,800 ppm PFOA, 500 (low) and 1,800 (high) ppm PFOA, or 5 ppm E2 in the diet compared with control animals. Supplemental raw data files are available online through Gene Expression Omnibus accession no. GSE7837 (NCBI 2008b). Array hybridizations were performed with a common reference sample using dye swapping, and final fold-change values were calculated as a ratio to control animals. Bidirectional hierarchical clustering of genes differentially regulated in at least one treatment group (Figure 2A) indicated similarities in the transcriptional profiles for E2, PFOA, and DHEA treatments. This is supported by pairwise analysis of all 1,672 features on the array using Pearson correlation, which demonstrated strong correlations in gene patterns between E2 and low PFOA, high PFOA, and DHEA [R = 0.69, 0.81, and 0.79 (two-tailed p < 0.0001), respectively] (Figure 2B). In contrast, gene profiles from CLOF had a low correlation with E2 (R = 0.26) and high PFOA (R = 0.45). Genes were considered differentially expressed if their mRNA levels changed ≥1.8-fold compared with controls (p < 0.05) among biological replicates (Table 3). Transcriptional profiles for PFOA were typical of an estrogenic response in trout liver (Tilton et al. 2006) and strongly overlapped with the profile for E2 as determined by principal component analysis applied on condition (Figure 2C). Transcripts encoding vitellogenic liver proteins were the most sensitive markers for the estrogenic response in trout; however, a number of genes important for cell proliferation, protein transport, immune function, and metabolism were also differentially regulated by PFOA, DHEA, and E2 treatments. Interestingly, PFOA did not regulate many genes in common with CLOF, another PPAR agonist. CYP2K5 was significantly up-regulated by both CLOF and PFOA and was down-regulated by E2 and DHEA. Microarray transcripts for carnitine palmitoyltransferase II, acetyl-CoA acetyltransferase 2, and catalase, as measures of β-oxidation and hydrogen peroxide generation, were not differentially regulated (up or down) by treatment with the PPs or E2, supporting the lack of treatment-related elevation of peroxisomal enzyme activities observed in trout (Table 3). The ability of PFOA and DHEA to alter serum E2 concentrations was explored as a possible mechanism for their estrogenic activity. Serum E2 was significantly elevated in animals fed 5 ppm E2 or 750 ppm DHEA in the diet for 14 days; however, serum E2 in PFOA-treated animals was not statistically different from control animals (Figure 1C), suggesting that the estrogenic effect of PFOA was not indirectly caused by altered serum E2 levels.

Expression of select genes differentially increased or decreased by microarray analysis, including CYP2K5, VTG, CYP1A3, CTSD, and ESRI, was confirmed by qRT-PCR using SYBR Green (Figure 3). Overall, we were able to confirm gene expression profiles measured by oligonucleotide microarray analysis using qRT-PCR. These data indicate that our strict criteria for determining differential gene regulation by array resulted in detection of meaningful changes that could be validated by other methods.

### Discussion
This study is the first report of tumor enhancement by PFOA in a model that is insensitive to peroxisome proliferation. Tumor promotion was not related to the function of PFOA as a PP or PPARα agonist but was phenotypically linked to estrogenic gene signatures in trout liver. The lack of tumor enhancement by CLOF is also a novel observation in trout and is supported by data indicating that another potent PP and PPARα agonist, Wy-14,643, does not enhance tumor incidence in trout after chronic exposure postinitiation (Carpenter H, personal communication). The tumor response to DHEA was similar to that published previously by our laboratory and confirms that DHEA is both a complete hepatocarcinogen and a tumor promoter in trout without inducing peroxisome proliferation (Orner et al. 1999). Chronic PFOA exposure causes liver tumors in rats and is associated with increased hepatomegaly, increased hepatic β-oxidation activity, and no change in hepatic cell proliferation (Biegel et al. 2001). These effects are typical of PPs in animals that are susceptible to

peroxisome proliferation and further include increased size and number of peroxisomes and induction of peroxisomal and microsomal enzymes involved in β-oxidation and ω-oxidation of fatty acids (Moody et al. 1991). In the present study, PFOA exposure in trout resulted in hepatomegaly but no increase in the size or number of peroxisomes or in biochemical or transcriptional markers of peroxisome proliferation.

Compared with rodents, the effects observed in trout are more similar to those reported in nonhuman primates after oral exposure to the PFOA precursor ammonium perfluoroctanoate. In a study of male cynomolgus monkeys exposed to 3–30 mg/kg/day for 26 weeks, Butenhoff et al. (2002) observed increased liver weights but little or no histopathologic evidence of liver toxicity, changes in enzyme markers of peroxisome proliferation, or changes in serum hormone levels. The increase in monkey liver weights was attributed in part to hepatocellular hypertrophy between trout and primates and some differences in the mechanism for liver hypertrophy, as measured by proliferating cell nuclear antigen (PCNA), was not elevated in cynomolgus monkeys or trout after chronic exposure. One notable exception may be that cell proliferation, as measured by proliferating cell nuclear antigen (PCNA), was not elevated in cynomolgus liver at the end of 26 weeks, even though PFOA was detected in both liver and serum (Butenhoff et al. 2002). Although PCNA was not measured in the present study, previously it has been found to be induced in trout liver after 2-week exposure to DHEA, E2, and other compounds that result in estrogenic gene signatures (Orner et al. 1996; Tilton SC, unpublished data). The lack of PCNA as a proliferative marker in monkeys may indicate some differences in the mechanism for liver hypertrophy between trout and primates and should be further explored.

PPs are thought to cause cancer through the metabolism of long-chain fatty acids by the peroxisomal β-oxidation system, which generates hydrogen peroxide and can result in DNA damage. However, we found no evidence of oxidative stress after exposure to PPs in trout. Catalase was not increased by any PP treatment in this experiment. Glutathione peroxidase, another measure of oxidative stress, was only up-regulated by treatments that resulted in an estrogenic response and thus was not specific to the PP class of compounds. Interestingly, there were few transcriptional changes by PFOA in common with the other PPARα agonist, CLOF, and independent of E2. These changes included up-regulation of CYP2K5, prostaglandin D synthase, and to a lesser extent, carbonyl reductase. Although the function of CYP2K5 in trout is unknown, this gene was regulated by PPARα agonists and E2 in a manner that has been reported previously for CYP2K1, lauric acid ω-hydroxylase, which is known to be mediated by PPARα and shares approximately 80% sequence identity with CYP2K5 (Buhler et al. 2000; Kennedy et al. 2004). However, CYP2K1 itself was not transcriptionally regulated by any treatments in the present study, suggesting that these enzymes have different activities in trout liver. Both prostaglandin D synthase and carbonyl reductase are involved in the signaling and metabolism of prostainoids, a pathway that has been associated with development of

Figure 2. Hepatic gene expression analysis after dietary exposure to 0.1% DMSO (control), 500 or 1,800 ppm PFOA, 750 ppm DHEA, 1,800 ppm CLOF, or 5 ppm E2 for 14 days. PCA, principal components analysis. (A) Bidirectional hierarchical clustering of hepatic gene expression in trout by Euclidean distance. Results are shown as fold change (log2) of control of dye-swapped slides for biological replicates (n = three per treatment). Heatmap reflects expression profiles for genes differentially regulated 1.8-fold up or down (p < 0.05) in at least one treatment group. Red indicates up-regulation; green, down-regulation; black, unchanged expression; and grey, missing values. (B) Pairwise correlations of hepatic gene profiles; values are fold change (log2) compared with control and were plotted to generate Pearson correlation coefficients (R) among the treatments (p < 0.0001). Lines indicate least-squares linear regression. (C) PCA on condition. Symbols represent biological replicates (n = 3), and ovals indicate overlap among E2, PFOA, and DHEA treatments.
hepatocellular carcinoma involving cyclooxygenase-2 (Wu 2006). Therefore, PFOA exposure resulted in some transcriptional responses that were specific for PPARα agonists and distinct from E2; however, they were not correlated with tumor enhancement by DHEA and PFOA.

Previously, we found that rainbow trout are very sensitive to promotion of hepatocarcinogenesis by E2 and other estrogenic compounds (Nunez et al. 1989; Tilton et al. 2007). The mechanism by which PFOA induces an estrogenic response in trout liver is currently unknown; however, some links between PPs and estrogen-mediated carcinogenesis have been reported. For example, fibrates can stimulate the esterification of E2 with fatty acids, which promote the storage and prolonged release of E2 from fatty tissue, enhancing cell proliferation in mammary gland (Yu et al. 2001). However, this mechanism was not

relevant to PPs in trout liver because CLOF did not result in an estrogenic response. In other studies, the ability of PFOA to increase serum E2 by hepatic aromatase was correlated with the occurrence of rat Leydig cell tumors in the absence of peroxisome proliferation (Biegel et al. 2001). This mechanism is likely also irrelevant for PFOA in trout because it did not elevate serum E2. In comparison, serum E2 was increased after DHEA treatment, suggesting that DHEA induces an estrogenic response via indirect conversion of E2 by aromatase, as described previously (Benninghoff and Williams 2008). These data demonstrate that PFOA enhances tumorigenesis through an estrogenic mechanism unique among the PPs investigated in this study.

The potential for PFOA and other structurally similar perfluorinated chemicals to promote hepatocarcinogenesis via direct interactions with the trout hepatic ER is the subject

*DFCI Gene Index ID number of the tentative consensus or singleton expressed sequence tag sequence corresponding to the OSUrbt, version 2, microarray feature. *Data shown are the most significant BLASTX (NCBI 2008a); however, if an expressed sequence tag has no significant (E-value < 10−6) BLASTX hit, then the most significant BLASTN hit is shown. Genes have been categorized by function based on putative trout homolog using the Gene Ontology and OMIM databases (NCBI 2008b, 2008c). Animals were fed 0.1% DMSO vehicle (CON), 1,800 ppm CLOF, 750 ppm DHEA, or 500 or 1,800 ppm PFOA acid (low or high PFOA, respectively), or 5 ppm E2 in the diet for 14 days. *p < 0.05 by Welch’s t-test for genes regulated at least 1.8-fold.

Figure 3. Comparison of gene expression of CYP2K5, VTG, CTSD, CYP1A, and ESR1 measured by microarray and real-time qRT-PCR. Values are expressed as fold change (log2; mean ± SD) compared with vehicle control. Dashed lines indicate 1.8-fold change (± 0.847 log2).
of ongoing studies in our laboratory. Evidence for activation of ER by PFOA, perfluorooctyl sulfate, and several fluoro-
rotolomers is supported by data that the ER antagonist tamoxifen inhibits their estrogenic activity in primary tilapia hepato-
cytes in vitro (Liu et al. 2007). Up-regulation of ER-α and ER-β expression was also reported in human MCF-7 cells and Chinese rare minnow, respectively, after exposure to PFOA (Maras et al. 2006; Wei et al. 2007). However, PFOA does not transactivate human ER-α or ER-β or Japanese medaka ER-α in yeast two-hybrid assays, suggesting that either species selectivity in ER binding or indirect activation of ER may be occurring (Ishibashi et al. 2007, 2008). Cross-talk between nuclear receptors PPARα, PPARγ, and ER has been described in mouse uterus (Gunnin et al. 2004), and PFOA activation of other nuclear receptors, including constitutive androstane receptor and pregnenolone X receptor, was reported in PPARα-null mice, possibly leading to hemotagonyl in these ani-

mals (Anderson et al. 2007). Therefore, although the majority of the hepatic effects of PFOA are mediated by PPARα in PP-sensitive models, interaction of PFOA with other nuclear receptors, including ER, may be func-
tionally significant in liver of PP-insensitive models or in other target organs and merits further investigation.

It is clear that the specific mechanism for PFOA estrogenicity will be important in extrapolating these data across species; howev-
er, our current study provides evidence that animals lacking peroxisome proliferation activity are rather insensitive to carcinogenesis by PFOA. Only 50 mg/kg/day (1,800 ppm) PFOA resulted in tumor enhancement, indi-
cating that chronic exposure to high levels of PFOA are necessary to promote hepatocarcinogenesis in trout, which are sensitive to liver tumor promotion by estrogen. These doses are typical of those used in rodent car-
cinogenicity studies with PPARα agonists but higher than the low part-per-billion PFOA concen-
trations measured in human and environmen-
tal samples (Calafat et al. 2007; Houde et al. 2006). Although our study did not identify a threshold for the estrogenic effects of PFOA in trout liver, we observed only 26% overlap of gene signatures between 5 ppm E2 and 500 ppm (5 mg/kg/day) PFOA compared with 83% at 1,800 ppm PFOA. These data demonstrate that PFOA is a weak estrogen in trout, similar to observations from other models in which PFOA weakly induced ER gene targets and also antagonized the estrogenic activity of E2 (Liu et al. 2007; Maras et al. 2006). Further studies are necessary to evaluate the potential for PFOA-mediated carcinogenesis in other PP-insensitive species, and in light of the mechanism identified in this study, the consequences of hormone-
related effects by PFOA should be also con-
sidered in other tissues, models, and sensitive life stages.

Conclusions
We report the novel findings that PFOA can enhance hepatocarcinogenesis postinitiation in rainbow trout, a model that is insensitive to peroxisome proliferation. Tumorigenesis was not related to the function of PFOA as a PP or PPARα agonist and was not observed after treatment with CLOF. Rather, tumor out-
come was phenotypically linked to estrogen gene signatures in trout liver after molecular profiling, which showed excellent correlation with E2 and is a unique mechanism identified for PFOA in carcinogenesis.
