Abstract

Cluster states are a new type of multiqubit entangled states with entanglement properties exceptionally well suited for quantum computation. In the present work, we experimentally demonstrate that correlations in a four-qubit linear cluster state cannot be described by local realism. This exploration is based on a recently derived Bell-type inequality [V. Scarani et al., Phys. Rev. A, 71 042325 (2005)] which is tailored, by using a combination of three- and four-particle correlations, to be maximally violated by cluster states but not violated at all by GHZ states. We observe a cluster state Bell parameter of $2.59 \pm 0.08$, which is more than $7\sigma$ larger than the threshold of 2 imposed by local realism.

Multi-particle entanglement is a complex, and relatively unexplored landscape. For two qubits, there exists only one class of entanglement [1], for three qubits there are two classes of genuine three-particle entangled states [2, 3], and for four qubits at least nine different classes of entanglement have been identified [4]. Recently, a great deal of attention has been devoted to a class of multiparticle entangled states called cluster states. This attention is largely due to the application of cluster states in Raussendorf and Briegel's "one-way" model for universal quantum computation [5]. In that model, one can drive a quantum computation entirely through single-qubit measurements and feedforward instead of unitary evolution. In addition to being a practical alternative to the standard model for quantum computing, it has also called into question the requirements for quantum computing and the relationship between measurement and dynamics [6]. One-way quantum computation based on cluster states demonstrating one-qubit gates, two-qubit gates, and a quantum search algorithm was recently realized experimentally [7].

Aside from their fascinating use for quantum computing, cluster states are a novel kind of multiparticle entangled states with fundamentally new and different properties. They share some properties with multi-particle extensions of both Greenberger-Horne-Zeilinger (GHZ) states $|\text{GHZ}\rangle = 1/\sqrt{2}(|000\rangle_{123} + |111\rangle_{123})$ [8, 9, 10] and W states $|\text{W}\rangle = 1/\sqrt{3}(|100\rangle_{123} + |010\rangle_{123} + |001\rangle_{123})$[2, 11, 12]. Each single-qubit constituent of a cluster state is completely mixed, characteristic of GHZ states. Also, any two of the four cluster-qubits can be projected into a Bell state by choosing an appropriate basis, similar to a GHZ state, but cluster states also share their persistence of entanglement [13] with the W states. Recent theoretical investigations of the "nonlocality" of these cluster states have constructed new types of Bell inequalities and even GHZ-type arguments to refute local realism with the specific correlations of cluster states in mind [14, 15].

Bell's inequalities are specifically designed to put quantum physics to the test against local realistic models. For two-qubit entangled states, the CHSH-Bell inequality [16, 17] is perhaps the best-known example. The inequality is constructed from two-qubit spin or, in our case, polarization correlation functions. Similarly, the Mermin inequality [18], testing local realism in three-qubit entangled states, is made entirely of three-qubit correlations. Its generalization is based entirely on N-qubit correlations [19]. In general, the choice of these correlations determines the optimality of a Bell inequality, i.e. whether entanglement is detected by a maximal violation of the inequality. For example, for the specific case of three qubits the inclusion of lower-order correlations can lead to an optimal Bell inequality for a W state, which could not detect GHZ entanglement [20]. This ambiguity and selectivity of which type of entangled state produces a maximal Bell violation makes the connection between entanglement and Bell's inequality tenuous especially in multi-particle states [21]. Nevertheless, it nicely highlights the fundamentally different ways in which the GHZ and W states manifest violations of local realism. Since the number of distinct classes of entanglement grows rapidly with the number of qubits, one might expect to find other Bell inequalities optimal for different states. Specifically, for a Bell inequality optimal for cluster states, lower-order correlations will be of importance, since cluster states can be generated by nearest-neighbor Ising interaction [5].

A recent theoretical work has found a GHZ-type argument for cluster states [14]. As in the original GHZ article [8], the new work showed that there exists a combination of observables whose expectation values cannot be consistent with a set of local realistic properties. However, in contrast to GHZ states, cluster states can even fulfill a GHZ argument using combinations of three- and four-qubit correlations [22]. This leads to the development of a Bell-inequality that can be maximally violated by cluster states but cannot be violated at all by GHZ states. In this experimental work, we use four-qubit cluster states encoded into the polarization state of photons to test that Bell inequality.

Linear cluster states arise when a line of qubits, each in the $|\pm\rangle$ state, where $|\pm\rangle = \frac{1}{\sqrt{2}}(|0\rangle \pm |1\rangle)$, experi-
ence nearest-neighbour CPhase operations, i.e., \( |j\rangle |k\rangle \rightarrow (-1)^{jk} |j\rangle |k\rangle \), \( j, k \in \{0, 1\} [5] \). Linear cluster states of two and three qubits are equivalent under local unitary transformations, or “locally-equivalent”, to Bell states and GHZ states, respectively [5]. In contrast, the four-qubit cluster is not locally equivalent to either the four-qubit GHZ or W states. In the present work, we use photon polarization to encode qubits with horizontal (vertical) polarization corresponding to \(|0\rangle\) (|1\rangle). Our target cluster state is of the form,

\[
|\phi_4\rangle = \frac{1}{2} (|HHHH\rangle_{1234} + |HHHV\rangle_{1234} + |VVHH\rangle_{1234} - |VVVV\rangle_{1234}),
\]

where the subscripts 1,2,3 and 4 label different photons in separated spatial modes. This state is locally-equivalent, under a Hadamard transformation \( H = \frac{1}{\sqrt{2}} (\sigma_X + \sigma_Z) \) on the first and last qubit, to the four-qubit linear cluster state

\[
|\phi'_4\rangle = \frac{1}{2} (|0+0+\rangle_{1234} + |0-1-\rangle_{1234} + |1-0+\rangle_{1234} + |1+1-\rangle_{1234}),
\]

where \(|\pm\rangle = \frac{1}{\sqrt{2}} (|0\rangle \pm |1\rangle)\) represents the complementary linear polarization. The linear cluster state, \(|\phi'_4\rangle\), has a set of 15 nontrivial stabilizer operators, \( S'_i \), each made up of products of four Pauli operators such that \( S'_i |\phi'_4\rangle = \pm |\phi'_4\rangle[14] \). Since each of the Pauli operators, \( \sigma_X, \sigma_Y, \sigma_Z, \) and \( \sigma_0 \), has eigenvalues of \( \pm 1 \) (\( \sigma_0 \) is the identity), each such stabilizer operators represent a property of the state that is fulfilled with certainty, i.e. an element of physical reality [23]. Following the reasoning of GHZ one can then find sets of 4 of these stabilizers, e.g., \( \sigma_2 \sigma_Y \sigma_4 \sigma_Z, \sigma_2 \sigma_Y \sigma_4 \sigma_X, \sigma_0 \sigma_2 \sigma_Y \sigma_Z, \sigma_0 \sigma_2 \sigma_Y \sigma_X \), with expectation values \(+1, -1, +1,\) and \(+1\), which are inconsistent with local realism. In addition, these stabilizers can be used to construct a Bell inequality. Since \(|\phi'_4\rangle\) and \(|\phi_4\rangle\) are equivalent only up to local transformations, the stabilizer operators required for the GHZ argument need to be interconverted. Obviously, the GHZ argument and Bell inequality, remain intact. Making use of the relations \( H \sigma_X = \sigma_Z H, H \sigma_Z = \sigma_X H, H \sigma_Y = -\sigma_Y H, \) and \( H \sigma_0 = \sigma_0 H \), we can convert the four operators, \( S'_i \), to a new set, \( S_i \), to \( \sigma_0 \sigma_2 \sigma_Y \sigma_X, \sigma_0 \sigma_2 \sigma_Y \sigma_X, \sigma_0 \sigma_2 \sigma_Y \sigma_X, \sigma_0 \sigma_2 \sigma_Y \sigma_X \), and \( \sigma_0 \sigma_2 \sigma_Y \sigma_X \), where the expectation values for \(|\phi_4\rangle\) are \(+1, +1, -1,\) and \(-1\), respectively. These stabilizers can now be used to construct the Bell inequality optimized for our cluster state \(|\phi_4\rangle\). The Bell parameter, \( S_C \), is given by

\[
S_C = |\sigma_0 \sigma_2 \sigma_Y \sigma_X + \sigma_0 \sigma_2 \sigma_Y \sigma_X| + |\sigma_0 \sigma_2 \sigma_Y \sigma_X - \sigma_0 \sigma_2 \sigma_Y \sigma_X|.
\]

The assumptions of locality and realism put a limit on the strength of the correlations such that \( S_C \leq 2 \). However, since the four terms in the Bell inequality are stabilizers of the cluster state, with the last term having opposite sign, the cluster state can violate this bound up to the algebraic limit of this expression, i.e. \( S_C = 4 \). It is a curious fact that the GHZ state, which is often said to be a maximally-entangled multi-particle state, cannot violate this inequality. Notice that the four properties for the cluster state include not only four-particle correlations as in the original GHZ argument, but also three-particle correlations. Those terms involving a measurement of \( \sigma_0 \) of photon 1 completely ignore the state of polarization of that photon. Recall that in a GHZ state this trac-ing out of one of the qubits leaves the remaining state completely mixed with only classical correlations between qubits. This is not the case in the cluster state as its persis-tency of entanglement allows for some particles to be ignored before all entanglement is lost. Thus different classes of multiparticle entanglement can exhibit stronger violations of local realism depending on the nature of the correlations in the Bell inequality.

To create the cluster state, we use a method first demonstrated in reference [7]. For the experiment, we generate polarization-entangled photon pairs using type-II parametric down-conversion [24]. A UV-laser pulse with a central wavelength of 395 nm and a pulse duration of 200 fs makes two passes through a beta-barium borate (BBO) crystal which emits entangled photons into the forward pair of modes \( a \) & \( b \) and into the backward pair of modes \( c \) & \( d \) (Figure 1). Transversal and longitudinal walk-off effects are erased by compensating crystals, which exist of a half wave plate (HWP) implementing a 90° rotation and an additional BBO crystal. These compensators are placed in each of the four modes. Final HWPs, one in mode \( a \) and another in mode \( c \), and the tilt of the compensation crystal allows the generation of any of the four Bell states. The forward pair of modes \( a \) & \( b \) are coherently superimposed with the backward pair of modes \( c \) & \( d \) at the two polarizing beamsplitters (PBS) by adjusting the position of the delay mirror for the UV-pump. The preparation of the cluster state relies on all of the lowest-order processes which result in the simultaneous emission of four photons.

Recall that the PBS is a device which transmits horizontally polarized light and reflects vertically polarized light. If two photons enter a PBS from opposite input ports, they will only emerge separately if their polarizations are the same in the H/V basis. If two photons enter a PBS from the same input port, they only emerge separately if they are oppositely polarized in the H/V basis. In the present case, the source was aligned to produce the Bell state \(|\phi^-\rangle\) into modes \( a \) & \( b \) and \(|\phi^+\rangle\) into modes \( c \) & \( d \). If one pair of photons is emitted into modes \( a \) & \( b \) and another into \( c \) & \( d \), then, after the two PBSs, the four-photon state \(|HHHH\rangle_{1234} - |VVVV\rangle_{1234}\) is left, provided the photons emerge into four different output modes. Emission of
two pairs of photons in a single direction occurs with approxi- 
mately 99% probability, and contributes two more terms to the 
final state \(-|HHVV\rangle_{1234}\) coming from the first pass and 
\(+|VVHH\rangle_{1234}\) from the second. Provided that all of these 
processes are indistinguishable and their relative phases are fixed, 
the final state is a coherent superposition of all four terms. The 
 requisite \(\pi\)-phase shift on the \(-|HHVV\rangle_{1234}\) term to 
\(+|HHVV\rangle_{1234}\) was implemented using the HWP in mode \(a\). A HWP rotation 
by an angle, \(\theta\), modifies the amplitude of this term 
according to the relation \(-\cos 2\theta|HHVV\rangle_{1234}\), thus a 
rotation of larger than 45° adds the required phase shift. Note 
that this rotation also changes the amplitudes of the 
\(|HHHH\rangle_{1234}\) and \(|VVVV\rangle_{1234}\) terms by a factor of 
\(\cos \theta\). Single-mode fibre-coupled photon counters were 
used in modes 1-4 to detect the photons. Controlling the 
coincidence counting rates from the forward and back- 
ward pairs give the extra degrees of freedom to balance 
the four amplitudes in the state.

The required expectation values, comprising products of 
Pauli operators, were reconstructed from sets of multi-
particle polarization correlation measurements. Each of 
the 48 measurements was performed for 600 s using 
combinations of QWPs and linear polarizers in each of 
the 4 output modes (1-4). The Pauli operators \(\sigma_X, \sigma_Y, \sigma_Z\) 
were measured by projective polarization measurements, 
\(|H/V\rangle\) for the \(\sigma_Z\) operator, \(|+/-\rangle = \frac{1}{\sqrt{2}}(|H\rangle \pm |V\rangle)\) for 
the \(\sigma_X\) operator, and \(|R/L\rangle = \frac{1}{\sqrt{2}}(|H\rangle \pm i|V\rangle)\) for the 
\(\sigma_Y\) operator. For the linear polarization measurements 
the QWP was set parallel to the orientation of the polar-
izer, whereas for the circular polarization measurements, 
the QWP was fixed to +45° while the polarizer was 
horizontally- or vertically- oriented. In order to extract 
the expectation value, 16 (four-particle correlations) or 8 
(three-particle correlations) measurements are required.

Experimental imperfections, including partial distin-
guishability in the four relevant four-photon emission 
processes and phase instabilities, lead to imperfect cor-
relations which give some coincidence counts even when 
theory predicts none. For the three-particle corre-
lations, we removed the polarizer from mode 1. How-
ever, since the state preparation method was reliant upon 
prior-selection, four-fold coincidences were still collected. 
Those measurements made without the polarizer show an 
increase in the coincidence rate as well as an imbalance 
most likely due to changes in the sensitive single-mode 
spatial filtering.

The four extracted correlations are shown in Figure 
2. We obtained positive expectation values of 0.61 ± 
0.05, 0.59 ± 0.04 and 0.71 ± 0.04 for the measurements 
\(\sigma_X\sigma_Y\sigma_X\sigma_Y\), \(\sigma_X\sigma_Y\sigma_Y\sigma_X\) and \(\sigma_0\sigma_2\sigma_X\sigma_X\), respectively, 
and the negative value \(-0.69 ± 0.04\). for \(\sigma_0\sigma_2\sigma_Y\sigma_Y\). 
Adding these four correlations together according to the 
Bell inequality from Eq. 3 results in \(S_C = 2.59 ± 0.08\), 
where the uncertainty is due to Poisson counting statis-
tics. The threshold for a local realistic modeling of these 
correlations is \(S_C \leq 2\), which our experiment violates by 
7σ.

The remarkable entanglement properties of cluster 
states can be readily used for the alternative “one-way” 
model of quantum computing [5], as was recently demon-
strated experimentally [7]. Different from the two well-
known classes of multiparticle entanglement, GHZ and W 
type, the properties of cluster states, such as their robust-
ness against decoherence and their persistency of entan-
glement make them practical for experimental study and 
interesting for quantum foundations. In this experiment, 
we have addressed a question of more fundamental rather 
than practical interest, namely how the novel family of 
cluster states can be used to demonstrate the non-local 
facets of quantum physics. We investigated a new kind 
of Bell inequality based on a GHZ argument for cluster 
states. The inequality detects cluster state entanglement 
optimally, while GHZ states would not violate the in-
equality. Our experimentally-produced cluster violates 
the inequality by more than 7σ. Our result demonstrates 
how specifically tailored Bell inequalities (e.g. by using 
specific correlations of the state) can become a useful 
tool to tackle the interesting questions between multiparticle 
entanglement and quantum nonlocality.

Figure 1. Experimental setup for the generation of four-photon cluster states. An ultraviolet laser pulse passes twice through a nonlinear crystal which is aligned to produce polarization entangled photon pairs on both the first and second pass. Compensators (Comp) are placed in the modes \( a, b, c \), and \( d \) to compensate birefringent effects and half waveplates (HWP) in mode \( a, c \) to manipulate the emitted entangled pairs. In each output mode quarter waveplates (QWP) and polarizers (Pol) are placed to project onto any desired state. Including the possibility of double-pair emission and the action of the polarizing beam-splitters (PBS), the four components of the cluster state are prepared. The incorrect phase on the HHVV amplitude can easily be changed by using the HWP in mode \( a \). Using these processes and multiphoton coincidence post-selection, the four-photon cluster state \( |\phi_4\rangle \) is generated in modes 1-4.

Figure 2 Experimentally extracted polarization correlations. The cluster-state Bell inequality requires four different polarization correlations. These are extracted from a complete set of 48 four-fold coincidence measurements. The four-photon correlations, \( \sigma_X\sigma_Y\sigma_X\sigma_Y \) and \( \sigma_X\sigma_Y\sigma_Y\sigma_X \), are combinations of 16 coincidence rates, whereas the three-photon correlations, \( \sigma_0\sigma_Z\sigma_X \) and \( \sigma_0\sigma_Y\sigma_Y \), are combinations of 8 coincidence rates. Each measurement run was recorded for 600s. A quarter-wave plate and linear polarizer were used for each polarization projection. The polarizer could be completely removed for those cases where \( \sigma_0 \) was measured. The values for the correlations

\[ \sigma_X\sigma_Y\sigma_X\sigma_Y, \sigma_X\sigma_Y\sigma_Y\sigma_X, \sigma_0\sigma_Z\sigma_X \text{ and } \sigma_0\sigma_Z\sigma_Y \] are \((+0.61 \pm 0.05), (+0.59 \pm 0.04), (+0.71 \pm 0.04), \text{ and } (-0.69 \pm 0.04)\), respectively. Substituting these into the Bell inequality in Eq. 3 yields a Bell parameter, \( S_C=2.59 \pm 0.08 \), which violates the local realism threshold by more than 7\( \sigma \).
