Immune suppression in chronic hepatitis B infection associated liver disease: A review

Tian-Yang Li, Yang Yang, Guo Zhou, Zheng-Kun Tu

Abstract
Hepatitis B virus (HBV) infection is one leading risk factors for chronic hepatitis, liver fibrosis, cirrhosis and hepatocellular cancer (HCC), which are a major global health problem. A large number of clinical studies have shown that chronic HBV persistent infection causes the dysfunction of innate and adaptive immune response involving monocytes/macrophages, dendritic cells, natural killer (NK) cells, T cells. Among these immune cells, cell subsets with suppressive features have been recognized such as myeloid derived suppressive cells (MDSC), NK-reg, T-reg, which represent a critical regulatory system during liver fibrogenesis or tumourigenesis. However, the mechanisms that link HBV-induced immune dysfunction and HBV-related liver diseases are not understood. In this review we summarize the recent studies on innate and adaptive immune cell dysfunction in chronic HBV infection, liver fibrosis, cirrhosis, and HCC, and further discuss the potential mechanism of HBV-induced immunosuppressive cascade in HBV infection and consequences. It is hoped that this article will help ongoing research about the pathogenesis of HBV-related hepatic fibrosis and HBV-related HCC.

Key words: Hepatitis B virus; Hepatocellular carcinoma; Liver fibrosis; Regulatory T cells; Regulatory natural killer cells; Dendritic cells; Monocytes

INTRODUCTION

Despite the presence of vaccines and therapeutic drugs, hepatitis B virus (HBV) infection remains a major global health problem. More than 350 million people worldwide are chronically infected with HBV, and about 1 million people die each year from HBV-related complications[1]. Persistent HBV infection can lead to varying degrees of liver damage, which eventually leads to hepatitis, fibrosis, cirrhosis, and hepatocellular carcinoma (HCC)[2]. HBV belongs to the noncytopathic hepatic DNA virus family which only infect human and orangutan liver cells, and there is no evidence that the HBV can infect other non-hepatocyte cells[3]. HBV infection does not cause direct hepatocyte lesions, and the host’s immune response determines whether it clears the virus or induces liver disease. In contrast that HBV-infected adults often develop self-limiting and transient hepatitis, and 95% of infections end with virus removal and the establishment of protective antibodies, the vast majority of neonatal vertical transmission of HBV from mother to child develops into chronic infection[4]. While divergent factors are involved in its pathogenesis, chronic HBV persistent infection is a complex process involving the interaction of the host immune system with the virus, which causes the incapacitation of the innate and adaptive immune response[3]. How HBV regulates the innate and adaptive immune cells, leading to persistent virus infection and further consequences, continues to be a research hotspot. Therefore, in this review, we summarize recent findings regarding the function and impairment of innate and adaptive immune cells, and discuss the potential mechanism of HBV-induced immune suppressive cascade in HBV infection and HBV-related liver diseases.

HBV-INDUCED IMMUNE SUPPRESSION CONTRIBUTES TO PERSISTENT INFECTION

HBV induces immune suppressive monocytes/macrophages

Monocytes/macrophages are important natural immune cells found in peripheral blood and organ tissue, and play multiple roles in the innate and acquired immune responses[8]. Monocytes/macrophage interact with lymphocytes through inhibitory or activating surface molecules. HBV stimulates monocyte/macrophage secretion of transforming growth factor β (TGF-β)[6] and interleukin-10 (IL-10)[7], while inhibiting the secretion of tumor necrosis factor α (TNF-α) and IL-12 induced by toll-like receptor (TLR2)[8,9]. Our study of HBV infection in a humanized mice model found that HBV induces human monocyte/macrophage differentiation into M2 macrophages, expressing IL-10 and other inhibitory cytokines[10]. Recently, we found that the anti-inflammatory cytokines (IL-10 and TGF-β) and inhibitory cell surface molecules [Programmed death ligand 1 (PD-L1) and human leukocyte antigen (HLA)-E] expressed in monocytes in patients with chronic HBV infection were significantly higher than those of healthy control[11]. Further experiments in vitro showed that HBsAg or HBV directly induced the expression of PD-L1 and HLA-E and the secretion of anti-inflammatory cytokines of monocytes from healthy adults[11]. Our group recently reported that HBV induces monocyte production of inflammatory cytokines via TLR2/MyD88/NF-κB signaling and STAT1-Tyr701 phosphorylation and inhibits interferon (IFN)-α-induced stat1, stat2, and ch25h expression through the inhibition of STAT1-Tyr701 phosphorylation and in an IL-10-dependent, partially autocrine manner[12]. Therefore, HBV-induced suppressive monocytes/macrophages play a key role in the immune pathogenesis of chronic persistent infection.

HBV induces myeloid derived suppressive cells differentiation

Myeloid derived suppressive cells (MDSCs) are bone marrow-derived cell subsets
with inhibitory functions, which can be divided into two main subgroups as M-MDSC (CD11b+HLA-DRlow/CD14+CD15+) and PMN-MDSC (CD11b+CD14+CD15-) according to their phenotypic and morphological characteristics[15]. MDSCs were first discovered in tumor tissue and play a role in the development, metastasis and immune escape of tumors[14]. Recent studies have found that MDSCs play a critical role in chronic HBV infection. The level of peripheral MDSCs in chronic hepatitis B (CHB) patients was significantly higher than that of healthy adults, and the percentage of MDSC cells had a significant correlation with HBV load in the plasma of HBV patients[15] and the mouse model[16]. Moreover, HBV induces monocytes differentiation of into MDSCs through the signal transduction pathway such as ERK/IL-16/STAT3/Pi3K, thus inhibiting the activation and function of lymphocytes[20]. Drugs that target MDSCs could restore the responses of HBV-specific T cells from CHB patients ex vivo and prevent the increase of viral load in HBV mouse models[21,22]. In vitro, MDSCs secrete arginase and down-regulate the CD3ζ chain by missing arginine, thus inhibiting IFN-γ secretion from HBV-specific T cells[23]. In addition, MDSCs produce suppressive cytokines IL-10 to inhibit T-cell response in CHB patients[24]. MDSC not only directly inhibits T cell response through such mechanisms as arginase but also indirectly influences immunomodulatory function by inducing regulatory T cells (T-reg)[25,26].

**HBV impairs the maturation and function of dendritic cells***

Dendritic cells (DCs) are the professional antigen presenting cells, which process and present antigen to T cells, and are involved in the production of cytokines that influence T-cell polarization. The studies of DCs subsets in chronic HBV infection have primarily been limited to myeloid DCs (mDCs) and plasmacytoid DCs (pDCs), two populations isolated from the peripheral blood. The frequency of mDCs in CHB patients shows a reduction which could be recovered by antiviral therapy[27]. There is a positive correlation of intrahepatic mDC subsets with serum alanine aminotransferase (ALT) levels and a significant inverse correlation with plasma HBV load[28]. The frequency of CD80+ and CD86+ mDCs showed slight differences between CHB patients and healthy donors after in vitro maturation[29]. It was also reported that PD-L1 expression on mDCs was increased in patients with active hepatitis B[30]. Increased ALT levels correlated with increased PD-L1 expression on mDCs, and impaired IFN-α production by pDCs[31]. Although some studies have reported that the function and frequency of pDCs were analogous between CHB patients and healthy controls[32], it has been demonstrated that HBV infection in pediatric patients showed a decreased frequency of pDCs, and the numbers of pDCs were restored by antiviral therapy[30,31]. The expression of the OX40 ligand was reduced in highly viremic patients while the expression of CD40 and CD86 was elevated in pDCs from CHB patients. Decreased expression of OX40L on TLR9-L-activated pDCs from viremic patients with HBV blocks their ability to induce the cytolytic activity of natural killer (NK) cells[33]. Monocyte-derived DCs (MoDCs) from HBV patients were impaired resulting in a reduction in T cell production of IL-2, TNF-α, and IFN-γ because of lower IL-12 secretion[34]. In vitro, cytokine-induced human MoDCs maturation in the presence of HBsAg or HBV contributed to a significantly more tolerogenic DC phenotype as the reduced release of co-stimulatory molecules and IL-12 production as well as a T-cell stimulatory capacity, as evaluated by IFN-γ production and proliferation of T-cells[35].

**HBV impairs NK cell function and induces NK cell differentiation***

NK cells are another important innate immune cell, which can effectively and quickly identify and remove virally-infected cells without MHC restriction. NK cells are the major lymphocytes in the liver, accounting for about 30% of liver lymphocytes[36]. In the HBV transgenic mouse model, CD3NK1.1 NK cells were found to be the main infiltrating lymphocytes of liver inflammation[37]. Functional defects of NK cells were found in CHB patients, showing a deactivation state[38]. The high level of inhibitory cytokine IL-10 in chronic HBV infection has an obvious inhibitory effect on the production of IFN-γ by NK cells[39]. The function of NK cells can be restored by IL-10 and TGF-β neutralizing antibodies in CHB patients[40]. The immunomodulatory function of NK cells has received much attention in recent years. The IFN-γ secreting by NK cells promotes the function of CD4+ T cells and enhance Th1 polarization[41]. However, under appropriate stimulation conditions, NK cells secrete immunomodulatory factor IL-10[42,43]. IL-10+ NK cells secrete TGF-β and IL-13, but do not secrete IFN-γ[43]. Our study found that the anti-inflammatory cytokines (IL-10) and inhibitory cell surface molecules (PD-1 and CD94) expressed by NK cells in patients with chronic HBV infection were significantly higher than those of healthy adults. Further, in the co-culture experiment of monocytes and NK cells, HBV-induced suppressive monocytes were found to induce NK cell differentiation into regulatory NK cells (NK-regs) expressing anti-inflammatory cytokines IL-10 by
chemokines, further inducing the development of liver inflammation and fibrosis. These inflammatory mediators induce peripheral causing liver damage. HBV interacts with receptors such as TLR2/4, which are expressed on Kupffer cells to HBV-induced suppressive monocyte/macrophage in liver fibrosis. There have been few reports about the impact of HBV-induced immune suppression on fibrosis. Therefore, many studies are focusing on the immunopathogenesis of chronic HBV infection and the related liver fibrosis. HBV is the leading risk factor for liver cirrhosis and HCC. Liver fibrosis, which is a major global health problem for the lack of effective treatment, is caused by chronic liver injury of any etiology such as viral infection, alcoholic liver disease, and NASH. The associated signals of liver injury cause the activation of hepatic stellate cells (HSCs), the activated HSCs trans-differentiate into myofibroblasts, and become the main source of extracellular matrix in the liver, leading to liver fibrosis. It is thus generally believed that HSCs are essential in the progression of liver fibrosis. HBV is the leading risk factor for liver cirrhosis and HCC. Liver fibrosis is the early stage of liver cirrhosis and HCC, and can be reversed. Therefore, many studies are focusing on the immunopathogenesis of chronic HBV infection and the related liver fibrosis. There have been few reports about the impact of HBV-induced immune suppression on fibrosis.

HBV induces T cell exhaustion and regulatory T cell differentiation

Early studies have determined that the adaptive immune response, especially HBV-specific CD4+ and CD8+ T cell immune responses, play a crucial role in virus removal and the immune pathogenesis of hepatitis B. CD4+ T cells promote CTL responses and the production of neutralization antibodies, while CD8+ CTLs remove hepatocytes that are infected with HBV. IFN-γ and TNF-α secreted by T cells are critical cytokines that inhibit HBV replication. In CHB infection, HBV-specific CD4+ and CD8+ T cells did not respond adequately, also known as T cell exhaustion, showing a significant increase in the expression of co-inhibitory receptors PD-1, CTLA-4, TIM-3 and CD244 on the surface compared to a substantial decrease in cytotoxicity and cytokine secretion capacity. The long-term exposure to a high concentration of viral antigens is the direct cause of T cell immune tolerance and specific T cell exhaustion. Virus-specific T cells become gradually more exhausted with rising viral load and exhibit weakened effector function. Viral load reduction restores the proportion of T cells and the function of HBV-specific T cells.

T-regs are a special subset of CD4+ T cells that play a critical role in establishing and maintaining immune tolerance. It was reported that the proportion of peripheral CD4+CD25Foxp3+ T-reg cells in CHB patients was higher than that in healthy control and self-clearance of acute HBV infection, and was positively correlated with serum HBV load. In addition, the proportion of hepatic infiltrating T-reg cells increased in CHB infection. Multiple molecules participate in T-reg mediated immunosuppression, including CTLA-4, IL-10 and TGF-β. For example, IL-10 secreted by HBcAg-specific T-reg inhibited the secretion of IFN-γ from HBV-specific CD4+ T cells, and blockade of IL-10 restored the secretion of IFN-γ of HBV-specific CD4+ T cells. T-regs from CHB patients could inhibit the proliferation and IFN-γ production of autologous peripheral blood mononuclear cells (PBMC) mediated by HBV antigen stimulation ex vivo. Therefore, MDSCs and T-regs secrete a variety of effector molecules, directly or indirectly inhibiting T-cell responses, resulting in a chronic, persistent HBV infection.

Therefore, the innate immune cells (monocytes/macrophages, DCs, NK cells) and adaptive immune cells (CD4+, CD8+ T cells) are dampened in chronic HBV infection. As shown in Figure 1, HBV induces immune suppressive cells, such as MDSCs, NK-reg, and T-reg cells, to form an immunosuppressive cascade through inhibitory molecules, such as PD-L1, PD-1, IL-10, which contributes to chronic and persistent HBV infection.

DOES HBV-INDUCED IMMUNE SUPPRESSION CONTRIBUTE TO LIVER FIBROSIS?

Liver fibrosis, which is a major global health problem for the lack of effective treatment, is caused by chronic liver injury of any etiology such as viral infection, alcoholic liver disease, and NASH. The associated signals of liver injury cause the activation of hepatic stellate cells (HSCs), the activated HSCs trans-differentiate into myofibroblasts, and become the main source of extracellular matrix in the liver, leading to liver fibrosis. It is thus generally believed that HSCs are essential in the progression of liver fibrosis. HBV is the leading risk factor for liver cirrhosis and HCC. Liver fibrosis is the early stage of liver cirrhosis and HCC, and can be reversed. Therefore, many studies are focusing on the immunopathogenesis of chronic HBV infection and the related liver fibrosis. There have been few reports about the impact of HBV-induced immune suppression on fibrosis.

HBV-induced suppressive monocyte/macrophage in liver fibrosis

HBV interacts with receptors such as TLR2/4, which are expressed on Kupffer cells to produce a large number of inflammatory cytokines and chemokines (TNF, CCL2) causing liver damage. These inflammatory mediators induce peripheral monocytes to infiltrate into the liver, and then proliferate and differentiate into macrophages and exacerbate the production of inflammatory cytokines and chemokines, further inducing the development of liver inflammation and fibrosis.
HBV-induced suppressive monocytes/macrophage, on the one hand, produce immunomodulatory molecules (IL-10, TGF-β, PD-L1/2) that inhibit the anti-fibrotic effects of NK cells and T cells; on the other hand, they secrete cytokines such as PDGF and TGF-β to activate HSC, prompting HSC survival[63,64]. A recent report showed that peripheral and ascitic MDSC numbers increase in cirrhosis and HCC, but its role in such pathology was not determined[65]. Conceptually, HBV-induced MDSCs impair the anti-fibrotic function of both T cells and NK cells by inhibiting IFN-γ secretion through PD-L1 or CTLA-4[66]. MDSC also inhibited cytotoxicity of NK cells through PD-L1 or TIGIT[67,68], thus protecting activated HSC from NK cell killing.

HBV-induced suppressive NK cells in liver fibrosis

NK cells secrete IFN-γ that inhibit HSC activation by abrogating profibrogenic TGF-β signaling and induce activated HSC apoptosis[69,70]. In addition, NK cells play a key role in the limitation of liver fibrosis through cytotoxicity of activated HSC[71]. Our recent study found a novel mechanism by which NK cells kill HSCs through TRAIL-involved degranulation manner[72]. In HBV infection, HBV-induced suppressive monocytes induce NK cell differentiation into NK-reg with decreased production of IFN-γ and increased IL-10[11]. Thus, it seems that HBV-induced NK-reg could promote HSC activation. But there is no evidence of the interaction between NK-regs and HSC, although it has been reported that HSCs modulate NK cells through a TGF-β-dependent emperipolesis in chronic HBV infection[73].

HBV-induced T cell immunosuppression in liver fibrosis

IL-2 secreted by CD4+ T cells is important in mediating the anti-fibrotic function of NK cells, and is impaired in HIV/HCV co-infection, which causes rapid progression of liver fibrosis[74]. More likely, HBV-induced T cell immunosuppression may also impair the anti-fibrotic function of NK cell. T-regs directly suppress NK cell degranulation of HSCs through CTLA-4, TGF-β1 and IL-8, and indirectly protect HSCs from NK cell killing by inhibiting MICA/B expressed on HSCs through IL-8 and TGF-β1[75]. In HBV-infected patients undergoing surgery for HCC, hepatic Th17 cells and T-reg were heightened in patients with advanced-stage HBV-related hepatic fibrosis[76]. On the other hand, T-regs could attenuate liver fibrosis by suppressing inflammation[77]. The role of HBV-induced T-regs in fibrosis needs to be further determined.

DOES HBV-INDUCED IMMUNE SUPPRESSION LEAD TO HCC?

HCC is the fifth most prevalent cancer in men and the second principal cause of cancer deaths worldwide[78]. HCC prevalence is very high in China, but the morbidity of HCC has also rising in the United States over the past few decades[79,80]. Early diagnosis and surgical resection are still the key to potential treatment, however, most patients with HCC have advanced-stage tumors with poor prognosis. HBV is one of the major risk factors for HCC, especially in areas where HBV is endemic, such as China[81]. The clinical scope of chronic HBV infection ranges from asymptomatic
HBV-induced immune suppression has been well described by a number of different mechanisms for the different immune cells.

**HBV-induced MDSCs in HCC**

An increased frequency of CD14^+HLA-DR^low MDSCs was reported in both peripheral blood and tumor tissue of HCC patients. Depletion of MDSCs restores production of granzyme B by CD8^+ T cells and increases the number of IFN-γ producing CD4^+ T cells in HCC patients, suggesting that HBV-induced MDSCs inhibit T cell antitumor effect. However, the frequency of CD14^+PD-L1^+ MDSCs is only positively correlated with HBV DNA load at the HCC stage. Because of higher levels of PD-1^+ CD8^+ T cells in tumor tissues compared to nontumor tissues in HCC, PD-L1 expression induced by either HBV or HCC on monocytes/MDSCs could be associated with impaired T-cell function in HBV-related HCC although it has not been demonstrated whether HBV-induced suppressive monocytes were involved in pathogenesis.

**HBV-induced NK-reg cells in HCC**

NK cells from healthy donor PBMCs have significant cytotoxic function to HCC cell lines, and HepB3 cells transplanted in nude mice deficient of lymphocytes and NK cells (NOD/scid IL2RGNull) are significantly ostracized by i.p. administered NK cells in an NKG2D-dependent manner. It has been reported that PD-1 is highly expressed on peripheral and tumor-infiltrating NK cells from HCC patients, suggesting NK cell exhaustion and poorer survival. Since NK cells play a key role in immunological surveillance, HBV-induced NK cell suppression may play a crucial role in the pathogenesis of HBV-related HCC. As our recent findings, PD-L1/PD-1 and CD94/HLA-E signaling control NK cell differentiation to NK-reg cells which in turn inhibit the anti-viral function of T cells and NK cells. Whether HBV-induced NK-regs are correlated with immune pathogenesis of HCC remains unclear.

**HBV-induced T-reg in HCC**

Both the absolute numbers and proportion of CD4^+CD25^+ T-reg cells significantly increase in the edge region of the tumor, compared to the non-tumor region. In vitro, HuH7 cells inhibit CD4^+CD25^+ T-cell proliferation, promote CD4^+CD25^- T-cell proliferation, and enhance their suppressor ability. It seems that the induction of T-regs could be effected by not only the HBV infection but also by the HCC, because the increased CD4^+CD25^- Tregs population and upregulated T-reg-related genes are induced by HepG2.2.15. A decreased infiltration of CD8^+ T cells concurrent with abundant accumulation of T-regs was found in tumor regions compared with non-tumor regions. Increased Foxp3^+ T-regs not only means poor survival, but also presents a prognostic predictor in patients with early-stage HCC. It indicates that HBV-induced T-regs might be involved in immune pathogenesis of HBV-related HCC.

**CONCLUDING REMARKS**

Immune suppression induced by HBV infection has been well described by a number of different mechanisms for the different immune cells. HBV induces immune suppressive cells, such as MDSCs, NK-reg, and T-reg cells, through an immunosuppressive cascade. The excessive immunosuppression could contribute to an HBV persistent infection and the progression of liver fibrosis and HCC. Better understanding of the underlying mechanisms of HBV-related immune suppression will help to develop new therapeutic strategies for HCC patients.
understanding the immunopathogenesis of HBV-related hepatic fibrosis and HCC will be helpful for the intervention and management of HBV progression and the treatment of related end-stage liver diseases in the clinic.
