**Abstract**

Infectious diseases bear a great risk for populations of naïve host species. In the present article we inform about the first microscopic and molecular detection of the bird pathogen *Trichomonas gallinae* in the White-winged Snowfinch (*Montifringilla nivalis* subsp. *nivalis*). The emergence of trichomonosis in this highly specialised alpine bird species may pose a serious threat to its already declining population. Interspecies transmission of *T. gallinae* most likely occurred at a bird feeder in a Swiss mountain village. Monitoring of the disease and immediate measures to prevent its spread are urgently needed.

**Keywords** *Trichomonas gallinae* · Snowfinch · *Montifringilla nivalis* · Breeding population decline · High-elevation specialist · Epidemic · Bird feeder · Disease

**Introduction**

Host switches from one species to another have been reported for many avian pathogens (Marzal et al. 2011). The outcome of such an interspecies transmission depends on multiple factors like the pathogen’s virulence, the capacity of the host immune system to cope with the infectious agent, the efficiency of transmission and numerous environmental parameters influencing the physiological condition of the pathogen and the host. Consequences for newly infected species can thus hardly be assessed right after a spill-over event. In unfavourable cases naïve hosts face the emergence of an infectious disease. While it is the nature of emerging infectious diseases (EIDs) to pose a serious threat for the health of bird populations, in a handful of cases they might even drive species into decline and towards extinction (Daszak et al. 2000; Lawson et al. 2018). Small populations of endemic species are especially threatened by EIDs. For
example, avian pox and malaria likely played a major role in the extinction of several Hawaiian honeycreeper species (Atkinson and LaPointe 2009).

The flagellated protozoa *Trichomonas gallinae* (Rivolta 1878) is known since the end of the nineteenth century as a pathogen of birds (Stabler 1947). Infections with *T. gallinae* are referred to as trichomonosis typically causing yellow lesions located in the oral cavity, eyes, skull, pharynx, oesophagus and crop (Martínez-Herrero et al. 2020). The severity of the disease ranges from no clinical signs to multifocal lesions with ulcerations and/or systemic infections. Obstructions of the oesophageal/pharyngeal lumen interfering with food intake and breathing may be fatal even at an early stage of the disease (Stabler 1947). *Trichomonas gallinae* is mainly known from columbids and their predators. While pigeons and doves were found to have high prevalence of *T. gallinae* (i.e. 44.8%), less than 1% of infected individuals showed clinical signs (Sansano-Maestre et al. 2009).

In contrast to this outnumbering of subclinical infections, trichomonosis was pinpointed as a major mortality factor for the endemic and endangered Pink Pigeon (*Nesoenas mayeri*) on Mauritius (Gaspar da Silva et al. 2007). These findings indicate that susceptibility to infections with *T. gallinae* varies among bird species. On the other hand, distinct strains of *T. gallinae* differ in their virulence (Sansano-Maestre et al. 2009). Sequencing of three genetic markers, the 18S rRNA gene, the ITS1/5.8S rRNA/ITS2 region, and the Fe-hydrogenase gene, has been mainly used for molecular characterisation (Gaspar da Silva et al. 2007; Sansano-Maestre et al. 2009; Lawson et al. 2011; Ganas et al. 2014; McBurney et al. 2015; Chavatte et al. 2019; Rijks et al. 2019; Martínez-Herrero et al. 2020). Depending on the marker and whether single locus or multi-locus approaches are used, differentiation down to the species or even strain level is possible.

First cases of trichomonosis in songbirds were reported from Greenfinches (*Carduelis chloris*) and Chaffinches (*Fringilla coelebs*) in Great Britain (GB) in 2005 (Lawson et al. 2018). The following year the disease already caused epidemic outbreaks. *Trichomonas gallinae* was subsequently identified as the aetiologic agent of a novel EID in passerines, which was responsible for a continuous population decline in greenfinches of 66% between 2006 and 2016 in GB (Lawson et al. 2018). While the pathogen was also detected in other passerines, impact on populations was much lower for these species compared to greenfinches and chaffinches. The high susceptibility of finches in general is not restricted to Europe but New World fringillid species like the House Finch (*Carpodacus mexicanus*), the Purple Finch (*Carpodacus purpureus*) and the American Goldfinch (*Carduelis tristis*) are similarly affected (Anderson et al. 2010; McBurney et al. 2015). In Europe, a progressive spread of trichomonosis was documented. While in 2006, mortality of finches was greatest in western and central counties of England and Wales, the disease first spread to eastern England in 2007 and to Fennoscandia in 2008. It is believed that migrating birds (i.e. chaffinches) acted as carriers spreading the diseases to the mainland of Europe (Lawson et al. 2011). Later, local outbreaks of trichomonosis were reported from the Netherlands and northern Germany in 2009 (Peters et al. 2009), central and western France in 2010 and 2011 (Chavatte et al. 2019), respectively, Austria and Slovenia in 2012 (Ganas et al. 2014) and northern France in 2017/2018 (Peters et al. 2009).

In the present article, we report the first detection of trichomonads in a formerly unaffected bird species belonging to the family Passeridae, namely the White-winged Snowfinch (*Montifringilla nivalis* subsp. *nivalis*; hereafter referred to as ‘snowfinch’). The snowfinch is highly adapted to the alpine environment, even enduring harsh winter conditions at elevations above 2000 m a.s.l. (Heiniger 1991). The subspecies has a disjunct breeding range above the treeline in the Cantabrians, the Pyrenees, the Alps, Corsica, the Apennines, and in the mountains of southwestern Balkans. Highly specialised alpine species, such as the snowfinch, are especially prone to suffer from habitat changes caused by climate warming (Resano-Mayor et al. 2019). Such changes might thus be a major factor for the negative population trends generally monitored throughout Europe. In Switzerland (harbouring 15% of the world population, see Keller et al. 2010), the number of snowfinches decreased over the past three decades by about one-third (Fig. S1).

**Methods**

In March 2019, diseased snowfinches and later dead individuals were observed at a bird feeder in Arosa, Switzerland (coordinates: 46.773° N 9.655° W). The carcass of one of these birds (collection date: 21.03.2019) was sent for routine post-mortem examination to the Centre for Fish and Wildlife Health (FIWI) of the University of Bern. The standard diagnostics included full gross and microscopic examinations as well as the detection of *Salmonella* spp. but no testing for avian influenza, as there was no evidence of an acute outbreak in the region at the time of sampling. Formalin-fixed paraffin-embedded (FFPE) material enabled molecular characterisation of the pathogen. DNA was extracted from the FFPE tissue using the ReliaPrep™ FFPE gDNA Mini-prep System (Promega). PCR amplification of the ITS1/5.8S rRNA/ITS2 locus as well as the Fe-hydrogenase gene and subsequent sequencing was performed as described elsewhere (Gaspar da Silva et al. 2007).
Results and discussion

In 2012, first cases of trichomonosis in greenfinches were detected by the FIWI (Table 1). After first detection in Swiss greenfinches local outbreaks became a reoccurring phenomenon (Table S1). Trichomonosis most likely contributed to the strong decline (i.e. 40% on the national level) of greenfinches over the subsequent years (Knaus et al. 2018). Several studies confirmed the aetiologic agent of trichomonosis in European passerines to be a clonal strain of *T. gallinae*, i.e., the A1 strain (Ganas et al. 2014; Lawson et al. 2018; Chavatte et al. 2019; Rijks et al. 2019). Introduction of this epidemic strain likely led to the spread of trichomonosis among Swiss greenfinches.

In March 2019, high morbidity and more than 20 dead snowfinches were reported from a bird feeder in the mountain village Arosa. The bird for which post-mortem examination was performed was in poor body condition with no fat reserves and attenuated wing muscle (Fig. 1a). Thickening of the mucosa and yellow plaques were observed in the oral cavity, cranial region of the oesophagus and crop (Fig. 1b). Histological examination of the tissue showed extensive erosions and ulcerations with accumulations of necrotic cell...
debris (Fig. 1c). Viable and degenerated inflammatory cells were observed, together with oval to round, pale, eosinophil protozoa (6–8 μm) with a small, basophilic nucleus (2 μm). Based on morphological features, they were tentatively identified as *Trichomonas* sp. (inset of Fig. 1c). Bacterial culture of the oesophagus was negative for *Salmonella* sp. Taken together, these findings provided evidence that the aetiological agent of the observed lesions was the detected protozoal organism *Trichomonas* sp.

Several attempts to amplify the Fe-hydrogenase gene were unsuccessful. In contrast, sequencing of the ITS1/5.8S rRNA/ITS2 locus resulted in a high-quality sequence of 326 bp (GenBank accession number LR898481). Phylogenetic analysis of the ITS region confirmed the species *T. gallinae* to be the microscopically detected protozoa. Further, the strain could be affiliated with the ITS sequence type ‘group A’. This group contains mainly pathogenic strains including the epidemic strain of European finches (Lawson et al. 2018). Even though strain identification was not unambiguous, distribution patterns, pathology and possible ways of transmissions suggested that the epidemic finch-trichomonad strain to be the causative agent of trichomonosis in snowfinches.

Food provisioning may support birds during harsh winter conditions, yet the inherent risk of pathogen transmission should be kept in mind. Infected individuals excessively produce saliva containing trichomonads (Stabler 1947; Lawson et al. 2018). Contaminated food and water are thus a main source for pathogen transmission at bird feeders. Even though snowfinches live above the tree line year round, in winter they may be forced by bad weather periods to seek out foraging grounds at lower elevations. In different areas, groups have learned to visit bird feeders in mountain villages. At these locations flocks of snowfinches get in close contact with typical garden birds. This is in line with our observation of numerous greenfinches regularly visiting bird feeders at 1900 m a.s.l. in Arosa (i.e. Swiss canton of the Grisons). In fact, one of the two highest breeding records of greenfinches in Switzerland originates from this mountain village (Knaus et al. 2018). Unfortunately, the practice of sending dead birds for post-mortem examinations varies considerably depending on the canton. Between the years 2010–2019 no greenfinches were sent for necropsy from the canton of the Grisons, but trichomonosis was detected in 5 greenfinches collected in the neighbour canton, the canton of St. Gallen (Table S1). A spill-over event in the winter 2018/2019 of *T. gallinae* from greenfinches (or other garden birds) to snowfinches at a bird feeder in Arosa seems thus likely. To prevent the spread of diseases at feeders, interspecific contact that might not regularly occur in the wild should be minimized and cleaning of feeders should be routine.

Preliminary findings of our study point out the immediate urgency to monitor *T. gallinae* in snowfinches. The potential risk of trichomonosis for this alpine subspecies with its small global population size and its endemic character is an issue of serious concern. While habitat changes due to climate warming (e.g. altered snow conditions, vegetation and temperatures) likely contributed to the ongoing population decline in snowfinches (Knaus et al. 2018; Resano-Mayor et al. 2019), trichomonosis acts as a novel factor potentially being harmful for the entire subspecies. To assess the impact of the pathogen on the naïve host, it is essential to elucidate distribution patterns of *T. gallinae* together with population dynamics of snowfinches in different mountains regions. In addition to such basic research, measures preventing the spread of the pathogen should be taken immediately. Hot spots of interspecies transmissions (e.g. bird feeders) should be detected and subjected to rigorous monitoring. This will allow to identify the infectious agent and anticipate outbreaks. Providing information to people feeding birds is an important first measure to prevent the spread of trichomonosis. Future research, which we aim to encourage with the present article, will reveal occurrence patterns of *T. gallinae* in snowfinches and the impact of trichomonosis on this characteristic species of the alpine environment.
