Classical theories of radiation reaction predict that the electron motion is confined to the plane defined by the electron’s instantaneous momentum and the force exerted by the external electromagnetic field. However, in the quantum radiation reaction regime, where the recoil exerted by individual quanta becomes significant, the electron can scatter “out of plane,” as the photon is emitted into a cone with finite opening angle. We show that Monte Carlo implementation of an angularly resolved emission rate leads to substantially improved agreement with exact QED calculations of nonlinear Compton scattering. Furthermore, we show that the transverse recoil caused by this finite beaming, while negligible in many high-intensity scenarios, can be identified in the increase in divergence, in the plane perpendicular to the laser polarization and wave vector, of a high-energy electron beam that interacts with a linearly polarized, ultraintense laser.

I. INTRODUCTION

Recent advances in the development of high-intensity lasers [1–3] and plasma-based accelerators [4–6] have made it possible to perform experiments on the interaction of charged particles with ultraintense electromagnetic pulses in regimes previously unexplored [7,8]. Earlier experiments relied on conventional accelerator technology [9,10]. The processes studied belong to the field of high-intensity particle physics [11–13], which combines quantum electrodynamics (QED) with the theory of strong electromagnetic (EM) background fields [14]. Of particular significance is photon emission, because the recoil it exerts can dominate the dynamics of electrons and positrons in high-field environments, including neutron-star magnetospheres [15] and laser-matter [16–18] or laser-laser [19–22] interactions in next-generation facilities [23–25].

Here we revisit how this fundamental process is modeled in simulations of particle dynamics in strong EM fields. In contrast to previous work, we employ a photon emission rate that is differential in scattering angle as well as energy, thereby resolving the beaming of the radiation around the emitting particle’s instantaneous velocity. As a result, the accuracy of simulations based on Monte Carlo implementation of localized emission events [26,27] is substantially improved, when benchmarked against exact QED predictions of nonlinear Compton scattering [28]. Simulations in the multiphoton, quantum radiation reaction regime demonstrate that including the beaming is important for accurate modeling of the emission of moderate-energy photons. The consequent transverse recoil may be neglected in many high-intensity scenarios, but is distinguishable in the increase in the divergence of an electron beam that collides with a linearly polarized laser pulse, for experimental parameters accessible with present-day technology. Furthermore, employing an angularly resolved spectrum permits quantitative estimation of the accuracy of the simulations in the low-energy part of the photon spectrum, where interference, i.e., nonlinear, effects become important.

In natural units $\hbar = c = 1$ (as used throughout), the photon emission rate per unit of proper time, energy $\omega$, and polar and azimuthal scattering angles $\theta$ and $\varphi$ is [29]

$$W^{(3)} = \frac{\partial^3 W}{\partial u \partial z \partial \varphi} = \frac{\alpha m u}{3 \sqrt{3} \pi^2 \chi (1 + u)^3} \times \left\{ \frac{z^2}{\chi (1 + (1 + u)^2) - (1 + u)} K_{1/3} \left( \frac{2 u z}{3 \chi} \right) \right\},$$

where $\alpha = e^2/(4\pi)$ is the fine-structure constant, $e$ is the elementary charge, $m$ is the electron mass, $u = \omega/(\gamma m - \omega')$, $z = (2\gamma^2(1 - \beta \cos \theta))^1/2$, and $K$ is a modified Bessel function of the second kind. The spectrum is controlled by the electron’s Lorentz factor $\gamma$ (velocity $\beta$) and quantum nonlinearity parameter $\chi = e|F_{\nu \nu}|p^3/m^3$. Here $F$ is the EM field tensor and $p$ is the electron momentum. The parameter $\chi$ may be interpreted as the ratio of the rest-frame electric-field strength to that of the critical field of QED $E_{cr} = m^2/e [30,31]$, or as the magnitude of the proper acceleration in natural units.

The radiation is strongly beamed around the particle’s instantaneous velocity if the particle is ultrarelativistic [14,32]. The mean-square angle of the power spectrum, $\langle \theta^2 \rangle = \int \theta^2 \omega W^{(3)} d\omega d\varphi/\int \omega W^{(3)} d\omega d\varphi$, is $\langle \theta^2 \rangle \approx 5/(4\gamma^2) \ll 1$ in the classical limit $\chi \ll 1$. It is larger in the quantum regime, growing as $\langle \theta^2 \rangle \approx 1.76 \gamma^{-2} \chi^{2/3}$ for $\chi \gg 1$, but still small. This justifies the standard approximation used in simulation codes that photons are emitted parallel to the particle momentum [26,27]. Nevertheless, its inclusion is warranted because the degree of beaming depends on the photon

---

*tom.blackburn@physics.gu.se
energy as well as the electron energy. The mean-square angle at fixed photon energy \( \omega' = \gamma m u / (1 + u) \), 
\[
\langle \theta^2(\omega') \rangle = \left( \frac{1}{3} \right)^{2/3} \left( \frac{m u}{\omega' \gamma} \right)^{2/3}, \quad \chi / u \gg 1
\]
\[
\chi / u \ll 1.
\]  
(2)

The lower the photon energy, the larger its emission angle: note that, for \( \omega' \ll \gamma m, u \approx \omega' / \gamma m \).

We have implemented a Monte Carlo algorithm that samples the triple-differential spectrum into a particle-tracking code, as an alternative to the standard method in which only the energy is sampled from the angularly integrated spectrum. These discrete emission events occur stochastically along the particles’ classical trajectories; between them, the dynamics are determined by the Lorentz force alone. The electron recoil on emission is fixed by the conservation of momentum. This “semiclassical” approach to QED is appropriate if the normalized amplitude of the field \( a_0 \) satisfies \( a_0^2 / \chi \gg 1 \), such that the formation lengths of the photons are much smaller than the timescale of the external field [14,33] and emission rates for a “locally constant” field can be employed.

We first confirm this by comparing the results of simulations which include the radiation beaming, with exact QED in Sec. II. We propose a conceptually simple way to estimate the magnitude of the error made by the locally constant field emission rate used in simulations. Then in Secs. III and IV we predict the beaming’s effect on the radiation spectrum and electron dynamics in experimentally relevant scenarios, where multiple photon emissions and the spatiotemporal structure of the focusing laser field are taken into account.

II. IMPROVED AGREEMENT WITH EXACT QED

Sampling the angularly resolved emission spectrum leads to substantially improved agreement with exact QED results. The interaction we consider is single nonlinear Compton scattering, i.e., the emission of one and only one photon by an electron in an intense, pulsed plane EM wave. The field tensor for the pulse is \( \mathbf{E}_0 = \sum_i k_0^i e_i^1 e_i^2 / (2 \pi) \), where \( (\psi_1, \psi_2) = (\cos \phi, \sin \phi) \cos^2(\theta / 2) \) for \( |\phi| \leq 2 \sigma, \phi \) is the phase, \( \delta = 1 \) and 0 for circular and linear polarization, \( k \) is the wave vector, and \( e_{1,2} \) are the polarization vectors along \( x \) and \( y \), respectively.

The one-photon emission probability is calculated in the framework of strong-field QED, which accounts for the interaction with the background electromagnetic field to all orders in \( a_0 \) [34–36]. The total probability, which can exceed unity, is interpreted as the mean number of emissions \( N_z \). As our Monte Carlo simulations allow for the emission of an arbitrary number of photons, equivalent results are obtained by postselection [28]: photon spectra are generated statistically using only those simulated emissions in which exactly one photon is emitted, and then rescaled to have the integral equal to the mean number of emissions, as determined from the full set of collisions.

A comparison between exact QED results and simulations that do and do not include the finite beaming of the radiation is presented in Fig. 1. Results are given in terms of the emitted photon’s normalized perpendicular momenta \( m r_{x,y} = k'_{x,y} (k p_0 / k k') \), where \( p_0 \) is the initial electron momentum. The \( r_{x,y} \) spectrum is effectively the angular profile of the emitted radiation if \( \gamma_0 \gg a_0 \gg 1 \), as \( r_{x,y} \simeq \gamma_0 \theta_{x,y} \) for \( \tan \theta_{x,y} = k'_{x,y} / (k k') \). We consider two examples: an electron with \( \gamma_0 = 3000 \) collides with a circularly polarized pulse with \( a_0 = 20 \), and an electron with \( \gamma_0 = 1 \times 10^4 \) collides with a linearly polarized pulse with \( a_0 = 25 \). \( \sigma = 3 \) and the central frequency \( \omega = k^0 = 1.55 \text{ eV} \) in both cases.

If the finite beaming is neglected, the calculated photon spectrum collapses onto a curve that traces the electron trajectory: \( m r_{x,y} = p_{x,y} / \gamma_0 \). This causes the angular spread of the radiation to be significantly underestimated [28]. By contrast, when the finite beaming is included [central column of Fig. 1(a)], we obtain excellent agreement with the QED results [right column of Fig. 1(a)]. The structure of the angular profile is reproduced in both the circularly and linearly polarized cases, as is shown by the lineouts along the axes \( r_x = 0 \) and \( r_y = 0 \) in Figs. 1(b) and 1(c).

Models based on localized emission, as ours is, are accurate for photons with energies \( \omega' / \gamma m \geq \chi / a_0^3 \). Low-energy photons, or those that are emitted in low-intensity regions of the pulse, have long formation lengths and interference effects tend to suppress their emission [38]. Hence we observe discrepancies near \( r_x = r_y = 0 \) in the circularly polarized case, because photons in this region originate from the pulse head and tail where the local value of \( a_0 \gg 1 \). Similarly, the spectrum in the linearly polarized case is broader in the \( r_x \) direction near the turning points \( \partial_y r_x = 0 \), where the local field vanishes.
can be calculated using the Frenet-Serret formalism, assuming that only electromagnetic forces are acting on the electron [40]. For all practical purposes, the curvature radius can be approximated as \( r_e \approx \frac{\gamma^2}{(m/c)^2} \), as is done in this paper. \( L_f \) can then be calculated for each simulated photon on emission, using the sampled value of the angle \( \theta \), and if it exceeds a specified maximum value the photon is not emitted.

Note that, because photons are only ever removed, this procedure does not account for constructive interference effects that could enhance photon emission. However, as it has been shown that the locally constant field approximation (LCFA) tends to lead to overestimation of the low-energy part of the spectrum [28,38,41], comparing the results from simulations with and without this formation length check provides a conceptually simple way to estimate the accuracy of the spectra predicted.

An example of this procedure is shown in Fig. 2, which gives spectra that are differential in \( f = k \omega / k p_0 \), the lightfront-momentum transfer fraction, and \( r_\perp = (r_x^2 + r_y^2)^{1/2} \), for the photon emitted in the collision of the electron with \( \gamma_0 = 1000 \) and a circularly polarized laser pulse with \( a_0 = 10 \) and \( \sigma = 3 \). All three simulations include the finite beaming of the radiation, but take different values of the maximum permitted formation length. Observe that the spectra without a maximum (blue lines) and \( L_f < \lambda / 10 \) (orange lines) bracket the exact QED result; the difference between the two illustrates the expected accuracy of the LCFA.

Figure 2(d) shows the double-differential spectrum at constant \( f = 2 \times 10^{-4} \), which lies in the region \( f \lesssim 2\gamma/a_0^2 \), where this accuracy is weakest. The estimated error is large, warning that substantial interference effects are expected, as visible in the exact QED result. In fact, the best agreement is obtained with a formation length cutoff of \( \lambda / 5 \) (green lines in Fig. 2), which lies in between the two extreme cases. It is similar to the result of a simulation using the “extended” photon emission rates derived by Ilderton et al. [39]. As this approach is based on gradient corrections to the LCFA, two filters are necessary: one for the correction, which is activated only for \( a_\perp \phi > c = \pi / 2 \), and a global filter ensuring positivity of the rate. Note that the extended rates are presented only in their angularly integrated form and thus we cannot compare the angularly resolved spectra shown in Fig. 2(d). We could obtain one by assuming collinear emission, but it would have a hard cutoff at \( r_\perp = a_0 = 10 \), which is not consistent with exact QED [28].

The finite formation length of the photon is a significant potential source of error in simulations based on localized emission rates [28]. If this length is comparable to the spatial scale of variation of the background field, nonlocal effects such as quantum interference become important. We now discuss how sampling the angularly resolved photon spectrum allows the magnitude of such effects to be estimated. Observe that, in the classical picture, the formation length of a photon emitted at angle \( \theta \) to the electron instantaneous momentum is the distance traveled by the electron before it has separated from the photon by at least \( \theta \) [see Fig. 2(a)]. This distance may be estimated locally as \( L_f \approx 2r_e \theta \), where the instantaneous radius of curvature of the electron trajectory

\[
r_e = \frac{\gamma^2 - 1}{\sqrt{m^2 \gamma^2 - m^2(c\vec{E} + \vec{B} \times \vec{B})^2 / E_{ee}^2}} \quad (3)
\]

The finite formation length of the photon is a significant potential source of error in simulations based on localized emission rates [28]. If this length is comparable to the spatial scale of variation of the background field, nonlocal effects such as quantum interference become important. We now discuss how sampling the angularly resolved photon spectrum allows the magnitude of such effects to be estimated. Observe that, in the classical picture, the formation length of a photon emitted at angle \( \theta \) to the electron instantaneous momentum is the distance traveled by the electron before it has separated from the photon by at least \( \theta \) [see Fig. 2(a)]. This distance may be estimated locally as \( L_f \approx 2r_e \theta \), where the instantaneous radius of curvature of the electron trajectory

\[
r_e = \frac{\gamma^2 - 1}{\sqrt{m^2 \gamma^2 - m^2(c\vec{E} + \vec{B} \times \vec{B})^2 / E_{ee}^2}} \quad (3)
\]
wavelength. Our approach optionally excludes such photons on physical grounds, putting error bars on theoretical predictions. This is complementary to the use of corrected LCFA rates [39,41–43], which aim to reduce the error rather than estimate its magnitude.

Thus far we have considered only the emission of a single photon, as this can be calculated within QED and so benchmarking of the angularly resolved LCFA rate Eq. (1) is possible. We now turn to the effect of the radiation beaming on the photon and electron spectra in more realistic scenarios, where we allow for multiple photon emission and spatiotemporal structure in both the laser pulse and electron beam.

III. BROADENING OF THE RADIATION ANGULAR PROFILE

In a head-on collision with an EM wave that is linearly polarized along x, neglect of the finite emission angle means that all photons have \( r_y = 0 \), confining the radiation emitted by an initially divergence-free electron beam to the laser polarization plane. In reality, photons are emitted with \( r_y \neq 0 \). Thus, as the initial divergence of the electron beam is reduced to zero, the photon divergence in the perpendicular direction (along \( y \)) saturates at a nonzero value.

This floor on the final divergence can be estimated analytically in the limit \( \chi \ll 1 \), where the mean-square polar angle of the instantaneous power spectrum is \( \langle \theta^2 \rangle = 5/(4\chi^2) \). The total variance of the radiation angular profile in the \( y \) direction, \( \delta_y^2 \), after the electron has passed through a pulsed plane wave, is obtained by integrating \( \frac{1}{2} \langle \theta^2 \rangle \) over the pulse temporal profile. Thus we have \( \delta_y^2 = \int \frac{1}{2} \langle \theta^2 \rangle P \, d\phi / \int P \, d\phi \), where \( P = a m^2 c^2 \chi^2/(3\omega) \approx \gamma (g(\phi) g(\phi)) \) gives the instantaneous radiated power (per unit phase), \( g(\phi) \) is the pulse temporal envelope, and \( g(\phi) \) is the electron Lorentz factor as a function of phase \( \phi \). We obtain the latter by solution of the Landau-Lifshitz equation [44], which accounts for the deceleration due to classical radiation reaction. Assuming that \( g(\phi) \) is slowly varying, this gives \( g(\phi) \approx g_0/[1 + 2a c^2 \gamma_0 \xi I(\phi)/(3m)] \), where \( I(\phi) = \int_0^\infty g^2(\phi) \, d\phi \).

Thus, \( \delta_y^2 = \delta_y^2 + 5(1 + \mathcal{R})/8\gamma_0^2 \), \( \mathcal{R} = 2a c^2 \gamma_0 \xi I(\phi)/(3m) \int_0^\infty g^2(\phi) \, d\phi \), and \( \delta_0 \) is the initial divergence of the electron beam. If the intensity profile \( g^2(\phi) \) is a Gaussian with full width at half maximum (FWHM) duration \( \tau \), \( \int_0^\infty g^2(\phi) \, d\phi = \omega \tau / \sqrt{\pi/4 \ln 2} \).

We compare this prediction to the results of three-dimensional (3D) simulations of laser-electron collisions. In contrast to our comparison with exact QED in Sec. II, these simulations account for multiphoton radiation-reaction effects as well as the spatiotemporal structure of the electron beam and focused laser pulse. The former is initialized with mean energy 500 MeV and root-mean-square (rms) energy spread 50 MeV, divergence \( \delta_0 = 0.5 \text{ mrad} \), and size \( \rho = 10 \mu\text{m} \). This corresponds to a normalized transverse emittance of \( \epsilon_x = \langle \gamma^2 \rangle (p_x^2/m^2) = 5.0 \text{ mm mrad} \). Much smaller emittances have already been measured in laser-wakefield accelerators [45,46]. The laser pulse has wavelength \( \lambda = 0.8 \mu\text{m} \), has duration 30 fs, is linearly polarized along \( x \), and is focused to a spot of size \( w_0 = 2.5 \mu\text{m} \) and peak intensity \( 2 \times 10^{21} \text{ W cm}^{-2} \). The fields in our simulations are calculated to fourth order in the diffraction angle [47].

The photon spectra for this scenario, resolved in \( \theta_y \) (the angle in the plane of polarization) and \( \theta_x \) (the perpendicular angle), are shown in Figs. 3(a) and 3(b): they are clearly broader in \( \theta_y \) when the beaming of the radiation is included. This demonstrates that the increase shown in the upper panel of Fig. 1 can survive more realistic interaction parameters. Furthermore, Fig. 3(b) shows that the angular spread increases as the photon energy is lowered, whereas the entirety of the radiation is confined to \( \theta_y \ll \delta_0 \) if emission is assumed to be collinear.

Figures 3(c) and 3(d) give the energy-weighted rms \( \theta_y \) of all photons, and only those photons with \( \omega' = 1 \text{ MeV} \), as a function of peak intensity, with all other parameters fixed. Both are in reasonable agreement with our theoretical predictions Eqs. (2) and (5), setting \( \gamma = 2\gamma_0 a_0 m / \omega' \) and setting \( \gamma = \chi_0 \) in the former. Note that it is possible for \( \delta_y > \delta_0 \) even if emission is assumed to be collinear, because this decreases the number of photons, while the scattered electrons are ponderomotively expelled from the focal spot in both the \( x \) and \( y \) directions. In principle, the radiation beaming is also evident in the plane of polarization. However,
We focus, therefore, on the case of linearly polarized: density maps (color scale, normalized to respective maxima) of (a) the energy radiated per unit solid angle and (b) the energy radiated per unit frequency and angle in the collision of a 500-MeV electron beam and a circularly polarized laser pulse with peak intensity $2 \times 10^{21} \text{ W cm}^{-2}$.

if $a_0 \gg 1$, the angular extent of the radiation in this direction is dominated by the $a_0 / \gamma$ contribution of the electron’s oscillation.

The range of photon energies where inclusion of the beaming is essential can be estimated as the range for which the typical emission angle is between two and ten times the global average of $\approx 1 / \gamma$. Using our earlier result, Eq. (2), this is $\chi / 870 \lesssim \theta \lesssim \chi / 7$, where $\omega' / (\gamma m) = u / (1 + u)$. For the parameters used in Fig. 3, this corresponds to photons with energies from 0.1 to a few MeV. Even though they individually contribute little to the total-energy loss, such photons are emitted in far greater numbers than their higher-energy counterparts. As discussed in Sec. II, simulations based on the LCFA tend to overestimate the yield of low-energy photons; thus we validate the results shown in Fig. 3 against simulations in which photons with formation length $L_f > \lambda / 10$ are discarded. This reduces the number of 1-MeV photons by 40%, but the additional broadening at this energy due to the finite beaming [Fig. 3(b)] and the total energy radiated per unit solid angle [Fig. 3(a)] are unchanged. Similarly, the angular widths given in Figs. 3(b) and 3(d) are unchanged to within 5%.

It is important to note that, if the laser is circularly rather than linearly polarized, there is no distinction between the two directions perpendicular to the wave vector. The electrons oscillate in $x$ and $y$ and therefore the radiation has a finite angular spread in both directions, even if the initial electron divergence is reduced to zero and the finite beaming is neglected. This is shown in Fig. 4, where we compare the energy emitted per unit solid angle by a 500-MeV electron beam colliding with a circularly polarized, plane-wave, laser pulse, with peak intensity $2 \times 10^{21} \text{ W cm}^{-2}$, wavelength $0.8 \mu\text{m}$, and duration 30 fs. (The electron beam has rms energy spread 50 MeV and divergence $\delta_\theta = 0.5 \text{ mrad}.$) Comparing Fig. 4 to Fig. 3, it is clear that a distinction between the two perpendicular directions is necessary to observe finite beaming effects. We focus, therefore, on the case of linear polarization.

IV. QUANTUM LIMIT ON THE ELECTRON-BEAM DIVERGENCE

We now turn to the consequences of noncollinear emission for the electron. The conservation of momentum requires that if the photon is emitted at some finite angle a recoil $\Delta p$ is exerted on the emitting particle in the direction perpendicular to its velocity. $\Delta p = \omega' \sin \theta \simeq \mu \sqrt{\gamma^2 - 1} / (1 + u)$ to leading order in $1 / \gamma$; its mean value is $(\Delta p)/m \simeq 3 \sqrt{3} \pi \mu / 40$ for $\chi \ll 1$ and 0.264 $\chi^{1/3}$ for $\chi \gg 1$. For the perpendicular component of the recoil to have a significant impact on the dynamics, it should be comparable in size to the electron’s transverse momentum $p_x = ma_0$. However, $(\Delta p)/p_x \simeq 0.4 \chi / a_0$ or $0.3 \chi^{1/3} / a_0 \ll 1$ in almost all high-intensity scenarios of interest. As such, it is safe to neglect the transverse recoil in models of quantum radiation reaction, even though the emission probability vanishes for $\theta \to 0$ and therefore the recoil is never antiparallel to the instantaneous velocity.

Nevertheless, the effect of this transverse recoil can be visible in the collision of an ultralow emittance electron beam with a high-intensity, linearly polarized laser pulse. This is because, in a plane wave, the momentum in the direction perpendicular to the polarization $p_z$ is preserved by the Lorentz force; under classical radiation reaction, it can only ever decrease. Concretely, the equations of motion for this scenario are $\frac{dp_z}{d\phi} = -2am\gamma^2 \chi / 3$ and $\frac{dp_x}{d\phi} = 0$ [44]. We have $p_z = p_{z,0}(kp/kp_0) \leq p_{z,0}$ by $\frac{dp_z}{d\phi} \leq 0$, where the equality applies in the absence of radiation reaction. If $p_z = 0$ initially, it remains so. This is no longer the case when the transverse recoil is included.

Provided that radiation losses are not too large, the electron emerges from the laser field with $kp \simeq 2\omega|p_z|$. Therefore the distribution of $\tan^2 \theta / \gamma_2$ vanishes for $\theta / \gamma_2 \gg 1$, and so the angular divergence is reduced to zero, the final divergence $\delta_\theta = (\theta_\gamma^2)^{1/2}$ saturates at a nonzero value.

This lower bound on the divergence is a pure quantum effect, arising from the finite number of emissions. This phenomenon will occur only in an ultraintense laser, as considered here, but also in a static magnetic field. In principle, the transverse recoil sets a lower bound on the emittance of an electron beam in a storage ring, in the direction parallel to the magnetic field [48]; however, this limit is typically four orders of magnitude smaller than the emittance in the plane of the orbit, and in practice is dominated by magnet alignment errors and other deviations.

To estimate the final divergence, we assume that the electron performs a random walk in $\theta_z$, so $\delta_\theta^2 = \int \frac{1}{2} (\theta_z^2) W_\theta \, d\phi$, where the electron polar scattering angle $\theta_z \simeq u \sqrt{\gamma^2 - 1} / \gamma$ and $W_\theta$ is the instantaneous rate of photon emission per unit phase. In the limit $x_e \ll 1$, $(\theta_z^2) \simeq 13 \sqrt{2} / (30 \gamma^2)$ and $W_\theta \simeq 5a_0 x_e / (4 \sqrt{3} \gamma \omega)$. Assuming that the temporal profile $g(\phi)$ is slowly varying, we find

$$\delta_\theta^2 = \delta_\theta^2 + \frac{26 \sqrt{3}}{27 \pi} \frac{a_0^2 \omega^2}{m^2} \int_{-\infty}^{\infty} g^3(\phi) \, d\phi,$$
