Far-field coherent thermal emission from polaritonic resonance in individual anisotropic nanoribbons

Sunmi Shin¹, Mahmoud Elzouka², Ravi Prasher²,³ & Renkun Chen⁴

Coherent thermal emission deviates from the Planckian blackbody emission with a narrow spectrum and strong directionality. While far-field thermal emission from polaritonic resonance has shown the deviation through modelling and optical characterizations, an approach to achieve and directly measure dominant coherent thermal emission has not materialised. By exploiting the large disparity in the skin depth and wavelength of surface phonon polaritons, we design anisotropic SiO₂ nanoribbons to enable independent control of the incoherent and coherent behaviours, which exhibit over 8.5-fold enhancement in the emissivity compared with the thin-film limit. Importantly, this enhancement is attributed to the coherent polaritonic resonant effect, hence, was found to be stronger at lower temperature. A thermometry platform is devised to extract, for the first time, the thermal emissivity from such dielectric nanoemitters with nanowatt-level emitting power. The result provides new insight into the realisation of spatial and spectral distribution control for far-field thermal emission.
Thermal radiation, as described by Planck’s law, is generally considered incandescent in classic textbooks. However, as Planck himself originally noted, the emitting energy distribution, including the broadband nature in both spectral and spatial domains, no longer holds if the characteristic size is smaller than the thermal wavelength ($\lambda_T \sim 10 \mu$m at room temperature). Recent rapid development in near-field radiative heat transfer\(^2\)–\(^6\) has revealed extraordinary behaviours when the distance between the emitter and receiver is smaller than $\lambda_T$, including giant enhancement in the heat flux and a coherent feature resulting from the tunnelling of evanescent waves by surface phonon polaritons (SPhPs) or surface plasmon polaritons (SPPs). Although coherence has been extensively investigated in the near field via evanescent waves, observation of coherence in far-field is still significantly limited. Far-field emission from an emitter with a size smaller than $\lambda_T$ can result in polarised thermal emission that could be relevant for broader applications for which the near-field gap is inaccessible\(^7\)–\(^11\). Recent work has shown the feasibility of spectral and spatial control of far-field thermal emission from engineered microstructures. For instance, Greffet et al. demonstrated coherent emission, featured with a narrow spectral and angular range, achieved by the grating of a polaritonic material (i.e., SiC) with a grating period comparable to $\lambda_T$ to couple to SPhPs\(^14\). More recently, through fluctuational electrodynamics modelling, Fernández-Hurtado et al.\(^15\) showed highly directional emissivity from anisotropic polaritonic structures, which was found to originate from the guided modes whose dispersion relation becomes highly dispersive around the Reststrahlen band. This feature resulted in super-Planckian thermal radiation between two anisotropic objects when they are oriented along the dominant emission direction, which was also experimentally demonstrated by Thompson et al.\(^16\).

These earlier findings provide important insights into the design of an emitter with coherent far-field thermal emission. To achieve dominantly coherent thermal emission in the far field, it is desirable to quench the incoherent emission. Bulk polar dielectric materials, such as SiO$_2$, generally behave like a blackbody in the broad infrared (IR) range, except within the Reststrahlen band\(^17\) (negative permittivity) that shows high reflectance (Fig. 1b). For SiO$_2$, the skin depth ($\delta$) at 10-µm wavelength is on the order of 1 µm\(^18\). Therefore, one could utilise an emitter smaller than $\delta$ to suppress the broadband emission. This volumetric absorption regime was theoretically studied by Golyk et al.\(^18\) for cylindrical SiO$_2$ and SiC nanorods, where the incoherent emission was greatly suppressed from the near-blackbody limit for rod diameters much smaller than $\lambda_T$, as shown in Fig. 1a. The thickness of the ribbons was fixed at 100 nm to suppress the broadband emission. We estimated the volumetric emissivity to be 0.062 for this thickness at room temperature, which is much smaller than the bulk emissivity (~0.9). The design of the width of the ribbon was dependent on $\frac{\lambda_{\text{SPP}}}{\delta}$. It should be noted that the wavelength of SPhPs at the SiO$_2$/vacuum interface is different from that in free space (~10 µm); it is dependent on the geometry of the SiO$_2$ ribbons because the dispersion of SPhPs is now controlled by the coupling between the optical phonon in SiO$_2$ and photons. We determined the dispersion of a thin film using the following analytical formula (see Supplementary Note 8):

$$\frac{\varepsilon_{\text{SiO}_2}}{\varepsilon_0} = -\frac{k_{\lambda_{\text{SiO}_2}}}{k_{\lambda_{0}}} \coth \left( \frac{\lambda_{\text{SiO}_2}}{2k_{\lambda_{0}}} \right),$$

where $\varepsilon_0$ and $\varepsilon_{\text{SiO}_2} (=\varepsilon' + \varepsilon'')$ are the permittivity in vacuum and SiO$_2$\(^28\), respectively; $k_{\lambda_0}$ is the transverse vector
A schematic illustration of a long nanoribbon with rectangular cross-section with thickness (t) and width (W). Here, t is thinner than the skin depth (δ), leading to significant transmitted intensity of the electromagnetic wave perpendicular to the ribbon (|E_y|) compared with the absorbed intensity (|E_z|). Otherwise, the optical response in the parallel direction to the plane would yield higher emission because the cross-sectional length scale with the integer multiples of half wavelength supports the localised resonance modes, enhancing the absorption cross-section. The conduction of SPhP supported by thin films of different thickness, calculated from the approximate solution Eq. (1). The energy range is within the Reststrahlen band. d SPhP wavelength and propagating length for a 100 nm thick thin film, corresponding to the dispersion curve.

\( k_z + k_y = \varepsilon k_0^2 \) in the medium; \( k_y \) is the propagating vector along the surface (\( k_y = q + i\kappa \)), where \( q \) and \( \kappa \) are the real and imaginary part of the momentum vector, respectively; and \( k_0 \) is the free space vector. Equation (1) is the solution for the even modes of two branches of the surface waves by electric fields at the top and bottom surfaces, and this case represents the dominant contributions for the efficient absorption by confining the energy from the free space into the small physical cross-section area. The confinement becomes more significant with a smaller thickness, due to the stronger interaction of the two symmetric evanescent surface waves (Fig. 1c). The analytical equations are summarised in the Supplementary Information (see Supplementary Note 8) for the major available fundamental modes by different polarisations (namely, symmetric TM, asymmetric TM, and TE modes). The calculated dispersions, shown in Fig. 1c, indicate that the wavelength of SPhPs ranges from 0.8 to 1.8 µm, which is approximately 5–10 times smaller than the free-space wavelength, for a SiO2 layer thickness of 100 nm. We designed the width (e.g., ~5 and 10 µm) to cover the integer multiples of the half wavelength of SPhP, to study the size effect on the resonant enhancement. The realised widths on the fabricated nanoribbons were 11.5 and 6.28 µm (Fig. 2).

Direct thermal emissivity measurement platform. We developed a microscale thermometry platform to measure the radiative heat loss of single SiO2 nanoribbons, as shown in Fig. 2a–f (see Methods for the detailed fabrication process). We used a suspended device such that the emission comes entirely from the nanoribbon without any influence of a substrate. We also implemented a modulated AC heating technique (Fig. 3b) to achieve sensitive thermometry with ~0.1 mK resolution. The basic idea to extract the radiative heat loss was to utilise the thermal fin model by systematically varying the length of the ribbons. Considering heat conduction along the length (L) of a nanoribbon with consideration of the radiative heat loss characterised by the heat transfer coefficient \( h \), where \( h = 4\sigma T^3 \) (\( \varepsilon \) is the emissivity, \( \sigma \) is the Stefan–Boltzmann constant, and \( T \) is the temperature), the temperature rise along the ribbon can be described by the fin model:

\[
\theta = \theta_f \cosh(mx) + \frac{\theta_s - \theta_f \cosh(mL)}{\sinh(mL)} \sinh(mx). \tag{2}
\]

Here, \( \theta (\equiv T - T_0) \) is the temperature rise from the ambient temperature \( T_0 \) as a function of the x-coordinate along the length (L); \( \theta_f \) and \( \theta_s \) are the temperature rise at the hot and cold reservoirs, respectively; and \( m \) is the fin parameter:

\[
m = \frac{hP}{\kappa A_c}. \tag{3}
\]

Here, \( \kappa \) is the intrinsic thermal conductivity of the ribbon, and \( P \) and \( A_c \) are the perimeter and cross-sectional area, respectively. The fin model notably allows us to quantitatively describe the combined energy transfer of light and heat in the form of radiation out of the surface and conduction through the volume. We summarise the temperature rise ratio of heating to the sensing
side, γ, as

$$\frac{\theta_i}{\theta_h} = \frac{1}{\cosh(mL) + \frac{G_b}{\kappa c m} \sinh(mL)} \equiv \gamma_{\text{lossless}}$$  \hspace{1cm} (4)

In the absence of radiative heat loss, m becomes 0; therefore, Eq. (4) can be simplified as

$$\frac{\theta_i}{\theta_h}_{m=0} = \frac{G_s}{G_b + G_s} \equiv \gamma_{\text{lossless}}$$  \hspace{1cm} (5)

where $G_s (=\kappa A_s/L)$ is the thermal conductance of the sample and $G_b$ is the thermal conductance of metal beams (see Supplementary Note 4). Finally, we can define the ratio of $\gamma$ to $\gamma_{\text{lossless}}$ as $\Delta (\gamma/\gamma_{\text{lossless}})$, where $\gamma_{\text{lossless}}$ is determined using short samples with bulk thermal conductivity. By comparing the $\Delta$ of samples with varying lengths, as shown in Figs. 2 and 3a, we can determine m and eventually $h$ and $\epsilon$.

The measured apparent thermal conductance includes the overall influences of both heat propagation through the solid volume and radiation out of the surface ($G_{\text{app}}$). To apply this measurement technique to low-dimensional materials, high-resolution thermometry is needed to resolve the radiative loss from the net thermal conductance. It is especially important to be able to detect the emissive power even with a small amount of heating, as we want to avoid a large deviation from the theoretical expectation. where the optical parameters are assumed to be identical to the values at room temperature. Using this novel approach, which bridges thermal and optical phenomena to measure the radiative heat loss, we were able to measure $\epsilon$ of a single isolated nanostructure, e.g., a nanoribbon, for the first time, without the effect of a substrate.

As a calibration of our fin technique to extract thermal emissivity, we also conducted a similar experiment with a rectangular beam cross-section which have larger thickness (~10 µm) than that of the ribbons as well as the skin-depth (~1 µm), such that the thermal radiation would follow the incoherent (broadband) bulk-like emission spectrum and the emissivity is expected to be close to the bulk value of SiO2 (~0.9 at room temperature). We extracted the emissivity using the fin model following the same procedure described above. Firstly, we designed the thick SiO2 length for 10 µm thick beams. To determine the suitable beam lengths to emphasize the radiative heat loss, we estimated thermal conductance by heat conduction and radiation with an assumed emissivity of 0.9. Supplementary Figure 5 shows that radiative conductance would be significant relative to heat conduction when the beam length is around 800 µm or longer. Thus, we fabricated the suspended SiO2 beams with various lengths, namely, 100, 400, 600, and 800 µm, as shown in Supplementary Fig. 6. With these various lengths, we measured thermal conductivity of the beams, as shown in Supplementary Fig. 7. We analysed temperature ratios between the heating and sensing sides, $\gamma$, at each length. At the smallest length (100 µm), we obtained thermal conductivity of 1.41 W m$^{-1}$ K$^{-1}$ at room temperature. At this length, the radiation is negligible (see Supplementary Fig. 5) and the measured thermal conductivity agrees well with the expected bulk value of SiO2. This validates our heat transfer measurements. By using the thermal conductivity value of the shortest beam or the bulk SiO2 (~1.4 W m$^{-1}$ K$^{-1}$), $\Delta$ was calculated as shown in Supplementary Fig. 7b. Using the same fin model that fits all the sample lengths with a single fitting parameter in the emissivity, we found the best fit with an emissivity value of 0.77 (±0.07) for the 7.5 µm wide and 10 µm thick beams. This value agrees well with the theoretical expectation. For example, Golyk et al. estimated an emissivity of around 0.7 for a cylindrical rod with 5 µm radius. The small discrepancy is likely due to the different cross-sectional geometries.

---

All the scale bars represent 30 µm.
(rectangular in our experiment vs. cylindrical in Golyk et al.) as well as the surface roughness of our samples.

**Apparent thermal conductivity of individual SiO₂ nanoribbons.** Because amorphous SiO₂ ribbons were used, we could calibrate the new measurement technique on short samples (e.g., L = 50 or 100 µm) with negligible radiative heat loss. SiO₂ is an ideal candidate to evaluate a new platform for heat-transfer measurement because it has very short phonon mean free paths (~1 nm at room temperature)⁵⁵,⁵⁶. Therefore, bulk-like thermal conductivity (1.3–1.4 W m⁻¹ K⁻¹ at 300 K) is maintained even at the nanometre scale, as experimentally confirmed by us on SiO₂ nanotubes with shell thicknesses down to 7.7 nm⁵⁷. For samples with longer length, γ would be larger, and the measured apparent thermal conductivity would deviate from the intrinsic κ of SiO₂, the difference in which is due to the radiative heat loss. Here, the apparent thermal conductivity is defined as \( \kappa_{\text{app}} = G_{\text{app}} L/A_w \) where

\[
G_{\text{app}} = G_b \frac{\theta_s}{\theta_h - \theta_s}.
\]  

When there is radiative heat loss (\( m > 0 \)), \( G_{\text{app}} \) in Eq. (6) deviates from the true \( G_c \). Thus, by comparing the measured \( \kappa_{\text{app}} \)
to the intrinsic value for SiO$_2$, we can directly illustrate the importance of thermal radiation.

Figure 3c, d shows the temperature-dependent $\kappa_{\text{app}}$. Indeed, we observed saturated phonon thermal conductivity in a relatively short length up to 100 $\mu$m, which is the same as the bulk value. $\kappa_{\text{app}}$ clearly decreased with longer lengths as a result of the enlarged radiative heat loss, which becomes more pronounced at higher temperature. In general, $\kappa_{\text{app}}$ with various lengths converges to the bulk value at lower temperature, indicating the reducing radiative heat loss, as expected.

Radiative behaviour of SiO$_2$ nanoribbons. We compared the relative change among samples with various lengths covering the conduction- and radiation-dominant regimes by utilising the $m$ parameter, which quantifies the degree of radiative loss. Figure 3e, f presents the experimental and fitted $\Delta$ values based on the fin model with two different widths, 11.5 and 6.28 $\mu$m, respectively. A longer ribbon resulted in lower $\Delta$ because of the larger radiation heat loss relative to the heat conduction. However, $\Delta$ was close to ~1 for the short samples (e.g., $L = 50$ and 100 $\mu$m) because of the negligible radiative loss. Similarly, we plotted $\Delta$ at different temperatures, and, as expected, higher temperature generated lower $\Delta$. To extract $\Delta$, we directly compared the experimental and fitted $\Delta$ values. We used a single $\Delta$ value to fit all the samples with the same width but different lengths. The dashed line in Fig. 3 represents the $\Delta$ value based on the averaged $\Delta$ value showing the best fit over the entire length range, and the shaded area indicates the uncertainty of the fitting. The uncertainty could originate from the slight variation in the actual widths of the fabricated samples with different lengths. Also, it may include the length-dependent behaviour with the nature of a broad range of propagating length as we shall see later. The temperature-dependent $\epsilon$ values were determined by repeating the same fitting process for all the samples measured at different temperatures. To avoid any contribution from the surroundings, we employed triple radiation shields in a vacuum chamber to ensure the surrounding temperature is the same as the sample temperature.

Figure 4 presents the extracted $\epsilon$ values at room temperature for ribbons with widths of 6.28 and 11.5 $\mu$m. In addition, the $\epsilon$ of a 100-nm-thick film was analytically calculated to provide a baseline for comparison with the ribbons (Supplementary Figs. 8–10). Here, we observed two effects associated with the low dimensions in SiO$_2$ nanoribbons. First, the effective $\epsilon$ of the ribbons was significantly lower than that of the bulk SiO$_2$ because the 100-nm thickness was much smaller than $\delta$ of SiO$_2$ (~1 $\mu$m at 300 K). However, more interestingly, a higher $\epsilon$ was observed for the nanoribbons than for a film of the same thickness. Furthermore, a larger enhancement in $\epsilon$ compared with the thin-film limit was observed for the ribbon with smaller width, 6.28 $\mu$m, which implies that a narrower width increases the resonance effect. These results can be explained by the localised resonant effect by SPhPs combined with the directional emission via the waveguided modes, which enhances $\sigma_{\text{abs}}$, as we shall discuss next.

Fig. 4 Enhanced emissivity with anisotropic nanoribbons. a Plots of the extracted emissivity at room temperature for ribbon widths of 6.28 and 11.5 $\mu$m, where the error bars are corresponding to the uncertainty in the fitting as shown in Fig. 3e, f. The grey bar represents the computed emissivity of an infinitely wide thin film of the same thickness as the ribbons, i.e., 100 nm. b Plots of directional emissivity ($\epsilon_{\text{dir}}$) of a nanoribbon with $W = 5 \mu$m at a wavelength of 9.5 $\mu$m, where the incoming plane wave has propagation $(k)$ directions where the polarisation directions are normal to $k$ in $x$-$y$ plane and $x$-$z$ plane, respectively for each $\phi = 90^\circ$ and $\theta = 90^\circ$ cases, and its incident angle is controlled by $\theta$ and $\phi$ as shown in the insets. c, d Enhanced absorption cross-sectional area as a function of wavelength, where the absorption cross-sectional area ($\sigma_{\text{abs}}$) is normalised by the geometrical cross-section ($\sigma_{\text{geom}}$) for various widths (c) and thicknesses (d).
Comparison with the broadband background thermal emission. We now analyse the contribution of the background broadband thermal emission, which is suppressed because of the small thickness (100 nm). In bulk SiO$_2$, the strong broadband absorption prevents the observation of further enhanced emission by polaritonic resonance. Therefore, a highly transparent (less absorbing) ribbon could signify the role of SPhPs in suppressing the broadband background, whose $\varepsilon$ was reduced to $\sim 0.062$ in the thin-film limit as shown in Fig. 4a. This significantly quenched background broadband $\varepsilon$ in the thin film provides the basis for dominantly coherent emission in the nanoribbon designs.

We now seek to understand the enhancement of the coherent emission in the nanoribbons, which was over 8.5-fold for the 6.28-µm-wide ribbon at 150 K compared with the thin-film limit calculated above. This enhancement is remarkable, considering that the spectral window for emission ($\omega_{\text{LO}}$) = 1251 cm$^{-1}$ to $\omega_{\text{LO}}$ = 1065 cm$^{-1}$ (or from 8 to 9.5 µm) is now much narrower compared with the broadband thermal spectrum. This enhancement can be understood from the strong resonant nature of the antenna-like nanoribbons, which results in an effective absorption cross-section ($\sigma_{\text{abs}}$) that is significantly higher than the geometrical one ($\sigma_{\text{geom}}$)\textsuperscript{15}. Fernández-Hurtado et al.\textsuperscript{15} suggested theoretical guidelines to overcome the far-field limit by Planck’s law and have systematically studied the far field radiation heat transfer from and between various subwavelength dielectric objects through the theoretical and numerical modelling. The computational study introduced the enhanced far-field thermal conductance between two anisotropic objects by increasing absorption efficiency, which was subsequently verified experimentally by Thompson et al.\textsuperscript{16} Similarly, we modelled $\sigma_{\text{abs}}$ of the nanoribbons using a finite element method (FEM) approach in COMSOL.

Here, two plane waves propagating along the length with normal polarisation were simultaneously exposed to evaluate their averaged contribution, as shown in the inset in Fig. 4c. The modelling results of $\sigma_{\text{abs}}$, as observed in Fig. 4c, indeed showed strong enhancement within the Reststrahlen band (Fig. 4c). The results are clearly distinguished from the lossy dielectric regime at around 12 µm wavelength. The peak enhancement factors ranged from 25 to 55 in ribbons of different widths. The enhancement increased when the ribbon width was reduced from 10 µm to 500 nm. From our results on the dispersion relations of SPhPs in a 100-nm-thick SiO$_2$ (Fig. 1c), the wavelengths of the SPhPs ($2\pi/q$) ranged from 0.8 to 1.8 µm at around 9 µm. Therefore, the ribbons with widths down to 500 nm, which is larger than half of the shortest SPhP wavelength, can still support localised resonance SPhP modes.

Our modelling results also indicate that further reduction of the ribbon width below 500 nm would rather lead to smaller enhancement. For example, the peak enhancement factor for 100 nm width is 45, which is smaller than that of the 500 nm width (~55), see Fig. 4c. This difference occurs because when the width is reduced to less than half the wavelength of certain modes of SPhPs, the localised resonance mode can no longer be supported within the width of the ribbons. Therefore, as the width decreases, a greater portion of the localised SPhP modes become unavailable. This result highlights the importance of the anisotropic nanoribbon design with suitable widths in maximising the resonance effect and resultant coherent thermal emission, as an isotropic cross-section such as that in a cylindrical rod would be unable to support certain resonance modes and consequently lead to a much smaller emissivity (e.g., $\varepsilon = 0.025$ in a 100-nm-diameter nanorod)\textsuperscript{18}. The geometry-dependent peak shift in the metallic regime indicates the coherent effect, as opposed to the monotonic change in the dielectric regime (near 12 µm wavelength).

We also modelled the enhanced $\sigma_{\text{abs}}$ with different thickness. The thicker ribbon would result in the less overlaps of two evanescent waves at the top and bottom surfaces. Therefore, it yields smaller enhancement as shown in Fig. 4d. The enhanced $\sigma_{\text{abs}}$ is closely correlated with the enhancement of the measured $\varepsilon$. Therefore, we can attribute the largely enhanced $\varepsilon$ from the nanoribbons to the coherent emission within the Reststrahlen band caused by the strong SPhP resonance.

Similar to the analytical model using a thin film, we also conducted mode analysis study of nanoribbons with the finite width and thickness. We compared the propagating vector of the thin film to that of nanoribbons calculated using COMSOL. The ribbon structure assumes infinite length and the $k_p$ is parallel to the length. The two finite dimensions in thickness and width resulted in multiple modes, as shown in Fig. 5. The dominant modes with high $q$ are very close to the dispersion of the thin film. Therefore, similar to the analysis from the thin film, it can be concluded that symmetric configurations of electric fields at the surfaces dominantly support the energy confinement. In addition, we observed the electric field intensity distributions at the cross-section of nanoribbons. Indeed, it showed high intensity along the width. The lowest order of modes, marked with the red circle, are well overlapped with the fundamental mode available from the dispersion relation of a thin film. For higher order modes, we could clearly observe the coherent resonance along the width (Fig. 5b). Please note that still the propagating direction is along the length, and the diverse forms of polarisation increase the number of modes. Although the higher order modes have lower $q$ values, still multiple modes possess significantly higher $q$, compared to the light line. Further, the shift in $q$ is smaller with the narrower width (Fig. 5b). Corresponding to the real part ($\sigma$) of propagating vector ($k_p = q + i\kappa$), we also studied the imaginary counterpart ($\kappa$). The propagating length was then calculated by 1/2x, shown in Fig. 5c. A broad range of propagating length from 100 ns to ~1 mm, can be supported. It implies that the anisotropic structure could have the length-dependent emissivity. In our experiments (Fig. 3e, f), the fitted lines assume a constant $\varepsilon$ over all the lengths up to 600 µm. The error range covers the potential length-dependent behaviour. All modelling in this study has been done with an infinite length, but more rigorous theoretical study, such as fluctuational electrodynamics\textsuperscript{15} could be a potential interesting study for the non-traditional far-field radiation.

In addition to the cross-sectional size-dependent emission, we modelled and compared the directional emissivity ($\varepsilon_{\text{dir}}$) of a nanoribbon and a film at 9.5-µm wavelength (e.g., $\omega_{\text{LO}}$ with the TE-polarised mode) using the finite-difference time-domain (FDTD) method, as shown in Fig. 4c. Compared with $\varepsilon_{\text{dir}}$ of the thin film (e.g., $\varepsilon_{\text{dir}} < 1$ in all directions), $\varepsilon_{\text{dir}}$ of the nanoribbon with 5-µm width was distinguishably enhanced with the larger incident angle $\theta$ with fixed $\phi = 90^\circ$ (see the $\theta$ and $\phi$ definition in the insets of Fig. 4c). The edges of the nanoribbon exposed to the incoming waves enhance the coupling of SPhPs, leading to the efficient emissive behaviour by the resonant modes. Similarly, as this nanoribbon is a 3D anisotropic structure, we also controlled $\phi$ (Fig. 4c) and observed further enhancement when the incident wave was close to parallel to the length. The higher absorption originates from the infinite length of the nanoribbon used in the model. These findings clearly demonstrate the merit of the anisotropic designs to selectively emphasise the coherent modes. Our observation for the enhanced emissivity over the thin film limit originates from the fact that the selective enhancement (in the spatial and spectral domains) outweighs the reduced absorption by the smaller volume, compared to the skin-depth (determined by $\lambda/4\pi k$, where $k$ is the imaginary part of the complex refractive index). This point is different from the previous study by Thompson et al.\textsuperscript{16} As we observed from the angle-dependent absorption cross-section, the most significant

The temperature dependence can be explained by the smaller peak shift in the Planckian behaviour was only determined by the temperature-independent optical parameter. Therefore, the observed in the broad range. The modelling results assumed a value near room temperature, corresponding to a thermal lifetime of ~10 µm (inset in Fig.6a). For the nanoribbons, the spectral emittance showed a peak within the Reststrahlen band, whereas significantly suppressed emission was observed in the broad range. The modelling results assumed a temperature-independent optical parameter. Therefore, the temperature-dependent behaviour was only determined by the peak shift in the Planckian distribution and showed a maximal value near room temperature, corresponding to a thermal wavelength of ~10 µm (inset in Fig. 6a). For the nanoribbons, however, we observed higher ε at lower temperature, up to 0.35 at 150 K for the 6.28-µm-wide ribbon (Fig. 6a). This unusual temperature dependence can be explained by the smaller k_B T, which increases the Q factor because of the smaller loss (lower ε″) at lower temperature. The damping term in the dielectric function in the form of the Lorentzian function is correlated with the lifetime of the optical phonons, which is smaller at lower temperature and leads to less broadening of the emission peak and stronger coherent emission; thus, the emissive behaviour would be temperature dependent. To quantify the coherent emission, we introduce a coherent enhancement factor (CEF) determined by the ratio of ε_{ribbon} to ε_{film} where ε_{ribbon} and ε_{film} are ε of a nanoribbon and film of identical thickness, respectively. As shown in Fig. 6b, the higher CEF observed at lower temperature is a very clear signature of the coherent mechanism. The maximum CEF achieved here was 8.5 for the 6.28-µm-wide ribbon at 150 K.

In summary, we studied the coherent thermal emission in the far field via anisotropic dimension control of polaritonic nanoribbons. The combination of heat-transfer measurements and optical modelling provided a new platform to precisely engineer and quantify the coherent thermal emission of an individual nanoscale object. This developed technique enabled us to determine that the anisotropic polaritonic nanoribbon design provides an extra degree of freedom to realise a nanoscale coherent thermal emitter with no design limitation in terms of its length. The thin structure effectively suppressed incoherent emission in the broad range of the spectrum, and the controlled width of the nanoribbon enhanced the coherent emission mediated by SPhPs. Furthermore, we observed a higher CEF (up to 8.5) at lower temperature, which clearly emphasises the dominant coherent emission in the nanoribbon structures. The upper limit of the CEF can be further improved by engineering the dispersion of the emitter. Use of the grating effect by periodically arranging the nanoribbons and/or metamaterials can lead to more confined surface modes by SPhPs with a higher Q factor. In addition, the spatial distribution of coherent thermal emission can be controlled by selectively limiting polarisation. Such coherent thermal emitters with a selective spectral/spatial band could find wide-ranging applications for thermal

management, energy conversion, bio/chemical sensing, light emission, and micro/nanomanufacturing[14,39–43].

Methods
Preparation and thermal measurement of SiO2 nanoribbons. To eliminate the potential impact of thermal contact resistance, the nanostructures were monolithically integrated with the thermal reservoirs. First, we prepared a 100-nm thermal oxide film on a Si wafer. Electrodes were patterned on top of the SiO2 layer using photolithography, and a metal layer (Ti/Pt 80 nm) was deposited by sputtering. After defining the patterned area with Cr based on the designed nanoribbon structures, the SiO2 layer was dry etched using CHF3 and Ar gas (Oxford Plasmalab DRIE) by SF6 gas (Oxford Plasmalab P100 RIE/ICP). This etching step provided a larger distance (~50 μm) between the Si substrate and SiO2 nanoribbons. After the DRIE, the Cr layers were removed with a Cr etchant, and the Si was treated with a buffer oxide etchant (BOE), followed by XeF2 etching to suspend the nanoribbons by removing the Si substrate underneath.

Fin model. A fin has high aspect ratios in dimensions to extend the surface area. Therefore, the temperature change along the length has the major contribution while it can be assumed that the temperature across the smaller dimension is constant. For this reason, the fin structure can possess the limited heat conduction and more effectively radiate heat, thus it has been widely used to cool devices as a heat sink[44].

The temperature profile can be described in Supplementary Fig. 2 by defining the temperature profile along the x-axis. The decaying rate is weighted by m, so-called fin parameter, and it is determined by

\[ m = \frac{hP}{\kappa A_x} \] (9)

\[ h \approx 4\sigma\epsilon T^3 \] (10)

where \( h \) is the heat transfer coefficient, \( \epsilon \) is the emissivity, \( \sigma \) is the Stefan–Boltzmann constant, and \( T \) is the temperature. Quantifying the m parameter enables to obtain the \( \epsilon \).

To specify the unknown parameters from the solution for \( \theta \), here we summarise the boundary conditions for temperatures at \( x = 0 \) and \( x = L \):

\[ \theta_{i=0} = C_1 \cosh(mx) + C_2 \sinh(mx) \] (7)

where \( C_1 \) and \( C_2 \) are unknown constants.

\[ \theta = T - T_0 \] (8)

The general solution introduces the feature of exponential temperature drop while propagating along the x-axis. The decaying rate is weighted by \( m \), so-called fin parameter, and it is determined by

\[ m = \sqrt{\frac{hP}{\kappa A_x}} \]

\[ h \approx 4\sigma\epsilon T^3 \]

where \( h \) is the heat transfer coefficient, \( \epsilon \) is the emissivity, \( \sigma \) is the Stefan–Boltzmann constant, and \( T \) is the temperature. Quantifying the m parameter enables to obtain the \( \epsilon \).

To specify the unknown parameters from the solution for \( \theta \), here we summarise the boundary conditions for temperatures at \( x = 0 \) and \( x = L \):

\[ \theta_{i=0} = \theta_{b} \] (11)

\[ \theta_{i=L} = \theta_{b} \cosh(mL) + C_2 \sinh(mL) = \theta_{s} \] (12)

Next, we summarise the boundary conditions for heat flux at \( x = 0 \) and \( x = L \). For heat flux at \( x = 0 \) (heating side),

\[ Q_b = -\kappa A_x \frac{\partial \theta}{\partial x} \bigg|_{x=0} = -\kappa A_x m C_2. \] (16)

For heat flux at \( x = L \) (sensing side),

\[ Q_s = -\kappa A_x \frac{\partial \theta}{\partial x} \bigg|_{x=L} = -\kappa A_x \left( m C_1 \sinh(mL) + m C_2 \cosh(mL) \right). \] (17)

Fi

The fin model can be described in Supplementary Fig. 2 by defining the temperature profile along the x-axis, parallel to the length, above the ambient temperature (\( T_0 \)) as below.

\[ \theta = C_1 \cosh(mx) + C_2 \sinh(mx) \] (7)

where \( C_1 \) and \( C_2 \) are unknown constants.

\[ \theta = T - T_0 \] (8)

The general solution introduces the feature of exponential temperature drop while propagating along the x-axis. The decaying rate is weighted by m, so-called fin parameter, and it is determined by

\[ m = \sqrt{\frac{hP}{\kappa A_x}} \] (9)

\[ h \approx 4\sigma\epsilon T^3 \] (10)

where \( h \) is the heat transfer coefficient, \( \epsilon \) is the emissivity, \( \sigma \) is the Stefan–Boltzmann constant, and \( T \) is the temperature. Quantifying the m parameter enables to obtain the \( \epsilon \).

To specify the unknown parameters from the solution for \( \theta \), here we summarise the boundary conditions for temperatures at \( x = 0 \) and \( x = L \):

\[ \theta_{i=0} = \theta_{b} \] (11)

\[ \theta_{i=L} = \theta_{b} \cosh(mL) + C_2 \sinh(mL) = \theta_{s} \] (12)

Next, we summarise the boundary conditions for heat flux at \( x = 0 \) and \( x = L \). For heat flux at \( x = 0 \) (heating side),

\[ Q_b = -\kappa A_x \frac{\partial \theta}{\partial x} \bigg|_{x=0} = -\kappa A_x m C_2. \] (16)

For heat flux at \( x = L \) (sensing side),

\[ Q_s = -\kappa A_x \frac{\partial \theta}{\partial x} \bigg|_{x=L} = -\kappa A_x \left( m C_1 \sinh(mL) + m C_2 \cosh(mL) \right). \] (17)

To meet the overall energy balance,

\[ Q_b = G_s \theta_b \] (18)

\[ -\kappa A_x \left( m C_1 \sinh(mL) + m C_2 \cosh(mL) \right) = G_s \theta_b \] (19)

\[ -\kappa A_x m \left( \theta_b \cosh(mL) + \frac{\theta_b - \theta_s \cosh(mL)}{\sinh(mL)} \cosh(mL) \right) = G_s \theta_b \] (20)

\[ \theta_b \cosh(mL) - \theta_b \cosh^2(mL) + \theta_b \left( \cosh(mL) + \frac{G_s}{\kappa A_x} \sinh(mL) \right) = 0 \] (21)

\[ -\theta_b + \theta_b \left( \cosh(mL) + \frac{G_s}{\kappa A_x} \sinh(mL) \right) = 0 \] (22)

\[ \frac{\theta_b}{\theta_s} = \frac{\sinh(mL) + \frac{1}{\kappa A_x} \cosh(mL)}{\cosh(mL) + \frac{1}{\kappa A_x} \sinh(mL)} \equiv \gamma. \] (23)

As shown in Supplementary Fig. 2c, the temperature profile become linear in the absence of heat loss (\( h = 0 \), and eventually \( m = 0 \)).

\[ Q_b = \frac{Q_b}{1 + \frac{G_s}{\kappa A_x} L} = \frac{G_s}{G_s + G_i} \theta_b \] (25)

\[ G_i (\theta_b - \theta_i) = G_s \theta_b \] (26)

\[ \theta_b = \frac{G_s \theta_s}{G_s + G_i} \] (27)

\[ \frac{\theta_b}{\theta_s} \bigg|_{m=0} = \frac{G_s}{G_s + G_i} \equiv \gamma_{lossless} \] (28)

Finally, we can define the ratio factor, \( \Delta \) as

\[ \Delta \equiv \frac{\gamma}{\gamma_{lossless}} = \frac{G_s}{G_s + G_i} = \frac{\kappa A_x}{\kappa A_x - \kappa A_x} \] (29)

where \( G_s \) is the measured apparent thermal conductance. By comparing the expected ratios of \( \gamma \) to the ratios of the measured conductivity, \( \epsilon \) can be extracted.
Heat transfer measurements. Nanoscale emitters with radiative heat loss generate very small signals. Therefore, we employed an AC-modulated joule heating and lock-in thermometry technique, as depicted in Fig. 3b, to improve the sensitivity. In addition, we used a Wheatstone bridge to measure the temperature at the sensing side with a high resolution down to ~0.25 pW K⁻¹. By measuring the RMS of the voltages at the heating and sensing sides corresponding to the modulated heating with 1σ angular frequency (i.e., Vₛ,heating and Vₛ, sensing, respectively), the temperature rise could be determined:

\[ \theta = Vₛ,\text{heating} \left( Rₐ + Rₚ + R₃ + R₄ \right) \frac{1}{Iₘ} \right) \left( \frac{dT}{dθ} \right) \]

\[ \theta = \frac{Vₛ,\text{sensing} \left( Rₚ \right)}{Iₘ} \right) \left( \frac{dT}{dθ} \right) \]

Here, \( Lₚ \) and \( Lₚ,\text{heating} \) are the AC-modulated input current to heating and DC current to the sensing beam, respectively; \( Rₚ \) and \( Rₚ,\text{heating} \) are the resistance of the heating and sensing beam, respectively; and \( Rₚ, \ R₃, \ \text{and} \ R₄ \) are the resistances of the Wheatstone bridge in Fig. 3b. Equations (30) and (31) are applicable in the low-frequency regime, where the heat penetration depth is much longer than the length of the suspended bridge (Supplementary Note 4). The measured temperature at the heating and sensing sides was inputted into Eq. (4) to obtain the parameter \( γ \). 

Here, \( \gamma,\text{heating} \) was determined from the short sample, which has negligible radiative loss compared with conduction by phonons. Finally, the experimentally measured \( \Delta (\equiv γ)\gamma,\text{heating} \) could be compared using Eq. (32) to extract the unknown parameter, \( m \) in the fin model, which allows both \( h \) and \( t \) to be determined:

\[ \Delta = \frac{\Delta,\text{heating}}{\Delta,\text{sensing}} \]

As the measurements were done in vacuum (10⁻⁶ Torr) and thus the convection and conduction of air are not important, \( h \) is only contributed by radiation heat loss, namely, only determined by the emissivity value. For each width, we used one single fitting parameter \( s \) to fit all the ribbon lengths from 100 to 600 μm (Fig. 3e, f). We also showed that the measured thermal conductivity values of the shortest ribbons (50 μm long) agreed well with the bulk value of amorphous SiO₂ (see Supplementary Fig. 3). At room temperature, the measured value is 1.4 W m⁻¹ K⁻¹. We note that at 50 μm length, the radiation heat loss is negligible compared to heat conduction along the ribbon, as the calculated \( Δ \) is very close to 1 even if the emissivity is 0.90 (see Supplementary Fig. 4). The thermal conductivity of amorphous SiO₂ is well known and is not expected to be influenced by the size range studied here (down to ~100 nm thickness in this case) because of the short phonon MFP in SiO₂ (<10 nm), as well documented in the literature. We have also previously shown bulk-like thermal conductivity of SiO₂ nanostripes (nanowires and nanotubes) with thickness down to ~7 nm. Therefore, we obtained bulk-like thermal conductivity of the ribbons (directly from the shortest, 50 μm long ribbon, and indirectly from the fitting to all the other ribbons) over the entire temperature range of 40–150 K. We also obtained bulk thermal conductivity value from short (100 μm) and thick (10 μm) SiO₂ beams (see Supplementary Fig. 7). These results validate our heat conduction measurements. In particular, the use of monolithic devices eliminates any potential thermal contact resistance between the ribbons and the thermal reservoirs, which have been a challenging issue in many nanowire thermal transport measurements using similar platforms.

Directional emissivity modelling. The emissivity of an infinite ribbon was estimated from the absorption cross-section, which was calculated numerically using 3D FDTD simulation (Supplementary Fig. 11). The ribbon was illuminated by a plane wave (emitted by a total-field scattered-field source), the profile of which in the frequency domain forms a Gaussian pulse, covering the frequency range in which SiO₂ has an appreciable extinction coefficient (55–280 Trad s⁻¹). The incident angle was manipulated to cover a hemisphere by changing the ribbon orientation angle, \( θ \), from 0° to 180° and the plane-wave travel direction, \( φ \), from 0° to 90° (see Supplementary Fig. 11). Because of the infinite length of the ribbon, we could accommodate the out-of-plane travel direction of the incident waves by applying Bloch periodic boundary conditions on the solution domain sides perpendicular to the direction along the length. For incident waves with \( φ \) ≠ 90°, we considered the frequency spectrum of the Gaussian plane wave, such that the deviation in the angle \( φ \) was below 5° for waves with different frequencies. The power absorbed by the ribbon was calculated by monitoring the net power flux crossing the boundary surrounding the ribbon in the time domain and then performing a Fourier transform to recover the absorbed power in the frequency domain. The spectral absorption cross-section was then calculated as the ratio between the absorbed spectral power and the plane-wave spectral source intensity. According to Kirchoff’s law, the directional and spectral emissivity, \( εₘₙ \), has the same value as the spectral absorption efficiency, which can be calculated from the ratio between the absorption cross-section, \( σₘₙ \), and ribbon projected area, \( σₘₙ,\text{geom} \) (assuming a ribbon of unit length):

\[ εₘₙ(\theta, \phi) = \frac{σₘₙ(\theta, \phi)}{σₘₙ,\text{geom}(\theta, \phi)} \]

Work at the Molecular Foundry was supported by the Office of Science, Office of Basic Energy Sciences, of the U.S. Department of Energy under Contract No. DE-AC02-05CH11231. This research used resources of the National Energy Research Scientific Computing Center (NERSC), a U.S. Department of Energy Office of Science User Facility operated under Contract No. DE-AC02-05CH11231. This research used the Lawrence computational cluster resource provided by the IT Division at the Lawrence Berkeley National Laboratory (Supported by the Director, Office of Science, Office of Basic Energy Sciences, of the U.S. Department of Energy under Contract No. DE-AC02-05CH11231).

Author contributions

S.S. fabricated the devices, performed the heat-transfer measurements, and modelled the absorption cross-section and mode analysis using COMSOL Multiphysics. M.E. calculated the directional emissivity of a thin film and nanoribbon using FDTD. R.C. and R.P. supervised the project. All the authors contributed to the discussion of the results and wrote the manuscript.
