Change Detection in Multivariate Datastreams: Likelihood and Detectability Loss

Cesare Alippi · Giacomo Boracchi · Diego Carrera · Manuel Roveri

Abstract We address the problem of detecting changes in multivariate datastreams, and we investigate the intrinsic difficulty that change-detection methods have to face when the data dimension scales. In particular, we consider a general approach where changes are detected by comparing the distribution of the log-likelihood of the datastream over different time windows. Despite the fact that this approach constitutes the frame of several change-detection methods, its effectiveness when data dimension scales has never been investigated, which is indeed the goal of our paper.

We show that the magnitude of the change can be naturally measured by the symmetric Kullback-Leibler divergence between the pre- and post-change distributions, and that the detectability of a change of a given magnitude worsens when the data dimension increases. This problem, which we refer to as detectability loss, is due to the linear relationship between the variance of the log-likelihood and the data dimension. We analytically derive the detectability loss on Gaussian-distributed datastreams, and empirically demonstrate that this problem holds also on real-world datasets and that can be harmful even at low data-dimensions (say, 10).

1 Introduction

Change detection, namely the problem of detecting changes in probability distribution of a process generating a datastream, has been widely investigated on scalar (i.e. univariate) data. Perhaps, the reason beyond the univariate assumption is that change-detection tests (CDTs) were originally developed for quality-control applications [1], and much fewer works address the problem of detecting changes in multivariate datastreams.

A straightforward extension to the multivariate case would be to independently inspect each component of the datastream with a scalar CDT [2], but this does not
clearly provide a truly multivariate solution, e.g., it is unable to detect changes affecting the correlation among the data components. A common, truly multivariate approach consists in computing the log-likelihood of the datastream and compare the distribution of the log-likelihood over different time windows (Section 2). In practice, computing the log-likelihood is an effective way to reduce the multivariate change-detection problem to a univariate one, thus easily addressable by any scalar CDT. Several CDTs for multivariate datastreams pursue this approach, and compute the log-likelihood with respect to a model fitted to a training set of stationary data: \cite{3} uses Gaussian mixtures, \cite{4, 5} use nonparametric density models. Other CDTs have been designed upon specific multivariate statistics \cite{6–11}. In the classification literature, where changes in the distribution are referred to as concept-drift \cite{12}, changes are typically detected by monitoring the scalar sequence of classification errors over time \cite{13–16}.

Even though this problem is of utmost relevance in datastream mining, no theoretical or experimental study investigate how the data dimension \(d\) impacts on the change detectability. In Section 3, we consider change-detection problems in \(\mathbb{R}^d\) and investigate how \(d\) affects the detectability of a change when monitoring the log-likelihood of the datastream. In this respect, we show that the symmetric Kullback-Leibler divergence (sKL) between pre-change and post-change distributions is an appropriate measure of the change magnitude, and we introduce the Signal-to-Noise Ratio of the change (SNR) to quantitatively assess the change detectability when monitoring the log-likelihood.

Then, we show that the detectability of changes having a given magnitude progressively reduces when \(d\) increases. We refer to this phenomenon as detectability loss, and we analytically demonstrate that, in case of Gaussian random variables, the change detectability is upperbounded by a function that decays as \(1/d\). We demonstrate that detectability loss occurs also in non Gaussian cases as far as data components are independent, and we show that it affects also real-world datasets, which we approximate by Gaussian mixtures in our empirical analysis (Section 4). Most importantly, detectability loss is not a consequence of density-estimation problems, as it holds either when data distribution is estimated from training samples or known. Our results indicate that detectability loss is a potentially harmful also at reasonably low-dimensions (e.g., 10) and not only in Big-Data scenarios.

2 Monitoring the Log-Likelihood

2.1 The Change Model

We assume that, in stationary conditions, the datastream \(\{x(t), t = 1, \ldots\}\) contains independent and identically distributed (i.i.d.) random vectors \(x(t) \in \mathbb{R}^d\), drawn from a random variable \(\mathcal{X}\) having probability-density-function (pdf) \(\phi_0\), that for simplicity we assume continuous, strictly positive and bounded. Here, \(t\) denotes the time instant, bold letters indicate column vectors, and ‘\(^\top\)’ is the matrix transpose operator.
For the sake of simplicity, we consider permanent changes $\phi_0 \rightarrow \phi_1$ affecting the expectation and/or correlation of $X$:

$$x(t) \sim \begin{cases} 
\phi_0 & t < \tau \\
\phi_1 & t \geq \tau 
\end{cases}, \text{ where } \phi_1(x) = \phi_0(Qx + v),$$

where $\tau$ is the unknown change point, $v \in \mathbb{R}^d$ changes the location $\phi_0$, and $Q \in O(d) \subset \mathbb{R}^{d \times d}$ is an orthogonal matrix that modifies the correlation among the components of $x$. This rather general change-model requires a truly multivariate monitoring scheme: changes affecting only the correlation among components of $x$ cannot be perceived by analyzing each component individually, or by extracting straightforward features (such as the norm) out of vectors $x(t)$.

2.2 The Considered Change-Detection Approach

We consider the popular change-detection approach that consists in monitoring the log-likelihood of $x(t)$ with respect to $\phi_0$:

$$L(x(t)) = \log(\phi_0(x(t))), \forall t.$$  \hspace{1cm} (2)

We denote by $L = \{L(x(t)), t = 1, \ldots, \}$ the sequence of log-likelihood values, and observe that in stationary conditions, $L$ contains i.i.d. data drawn from a scalar random variable. When $X$ undergoes a change, the distribution of $L(\cdot)$ is also expected to change. Thus, changes $\phi_0 \rightarrow \phi_1$ can be detected by comparing the distribution of $L(\cdot)$ over $W_P$ and $W_R$, two non-overlapping windows of $L$, where $W_P$ refers to past data (that we assume are generated from $\phi_0$), and $W_R$ refers to most recent ones (that are possibly generated from $\phi_1$). In practice, a suitable test statistic $T(W_P, W_R)$, such as the t-statistic, Kolmogorov-Smirnov or Lepage, is computed to compare $W_P$ and $W_R$. In an hypothesis testing framework, this corresponds to formulating a test having as null hypothesis “samples in $W_P$ and $W_R$ are from the same distribution”. When $T(W_P, W_R) > h$ we can safely consider that the log-likelihood values over $W_P$ and $W_R$ are from two different distributions, indicating indeed a change in $X$. The threshold $h > 0$ controls the test significance.

There are two important aspects to be considered about this change-detection approach. First, that comparing data on different windows is not a genuine sequential monitoring scheme. However, this mechanism is at the core of several online change-detection methods. Moreover, the power of the test $T(W_P, W_R) > h$, namely the probability of rejecting the null hypothesis when the alternative holds, indicates the effectiveness of the test statistic $T$ when the same is used in sequential-monitoring techniques. Second, that $\phi_0$ in (2) is often unknown and has to be preliminarily estimated from a training set of stationary data. Then, $\phi_0$ is simply replaced by its estimate $\hat{\phi}_0$. In practice, it is fairly reasonable to assume a training set of stationary data is given, while it is often unrealistic to assume $\phi_1$ is known, since the datastream might change unpredictably.

\textsuperscript{1} We do not consider changes affecting data dispersion as these can be detected by monitoring the Euclidean norm of $x(t)$.

3 Theoretical Analysis

The section sheds light on the relationship between change detectability and $d$. To this purpose, we introduce: i) a measure of the change magnitude, and ii) an indicator that quantitatively assesses change detectability, namely how difficult is to detect a change when monitoring $L(\cdot)$ as described in Section 2.2. Afterward, we can study the influence of $d$ on the change detectability provided that changes $\phi_0 \rightarrow \phi_1$ have a constant magnitude.

3.1 Change Magnitude

The magnitude of $\phi_0 \rightarrow \phi_1$ can be naturally measured by the symmetric Kullback-Leibler divergence between $\phi_0$ and $\phi_1$ (also known as Jeffreys divergence):

$$sKL(\phi_0, \phi_1) := KL(\phi_0, \phi_1) + KL(\phi_1, \phi_0) = \int_{\mathbb{R}^d} \log \frac{\phi_0(x)}{\phi_1(x)} \phi_0(x) dx + \int_{\mathbb{R}^d} \log \frac{\phi_1(x)}{\phi_0(x)} \phi_1(x) dx .$$

(3)

This choice is supported by the Stein’s Lemma [21], which states that $KL(\phi_0, \phi_1)$ yields an upper-bound for the power of parametric hypothesis tests that determine whether a given sample population is generated from $\phi_0$ (null hypothesis) or $\phi_1$ (alternative hypothesis). In practice, large values of $sKL(\phi_0, \phi_1)$ indicate changes that are very apparent, since hypothesis tests designed to detect either $\phi_0 \rightarrow \phi_1$ or $\phi_1 \rightarrow \phi_0$ can be very powerful.

3.2 Change Detectability

We define the following indicator to quantitatively assess the detectability of a change when monitoring $L(\cdot)$.

**Definition 1** The signal-to-noise ratio (SNR) of the change $\phi_0 \rightarrow \phi_1$ is defined as:

$$SNR(\phi_0 \rightarrow \phi_1) := \frac{\left( E_{x \sim \phi_0} [L(x)] - E_{x \sim \phi_1} [L(x)] \right)^2}{\var_{x \sim \phi_0} [L(x)] + \var_{x \sim \phi_1} [L(x)]} ,$$

(4)

where $\var[\cdot]$ denotes the variance of a random variable.

In particular, $SNR(\phi_0 \rightarrow \phi_1)$ measures the extent to which $\phi_0 \rightarrow \phi_1$ is detectable by monitoring the expectation of $L(\cdot)$. In fact, the numerator of (4) corresponds to the shift introduced by $\phi_0 \rightarrow \phi_1$ in the expectation of $L(\cdot)$ (i.e., the relevant information, the signal) which is easy/difficult to detect relatively to its random fluctuations (i.e., the noise), which are assessed in the denominator of (4). Note that, if we replace the expectations and the variances in (4) by their sample estimators, we obtain that $SNR(\phi_0 \rightarrow \phi_1)$ corresponds — up to a scaling factor — to the square statistic of a Welch’s $t$-test [22], that detects changes in the expectation of two sample populations. This is another argument supporting the use of $SNR(\phi_0 \rightarrow \phi_1)$ as a measure of change detectability.

The following proposition relates the change magnitude $sKL(\phi_0, \phi_1)$ with the numerator of (4).
Proposition 1 Let us consider a change $\phi_0 \rightarrow \phi_1$ such that
$$\phi_1(x) = \phi_0(Qx + v)$$
where $Q \in \mathbb{R}^{d \times d}$ is orthogonal and $v \in \mathbb{R}^d$. Then, it holds:
$$\text{sKL}(\phi_0, \phi_1) \geq \mathbb{E}_{x \sim \phi_0}[L(x)] - \mathbb{E}_{x \sim \phi_1}[L(x)]$$

Proof From the definition of $\text{sKL}(\phi_0, \phi_1)$ in (3) it follows
$$\text{sKL}(\phi_0, \phi_1) = \mathbb{E}_{x \sim \phi_0}[\log(\phi_0(x))] - \mathbb{E}_{x \sim \phi_0}[\log(\phi_1(x))] + \mathbb{E}_{x \sim \phi_1}[\log(\phi_1(x))] - \mathbb{E}_{x \sim \phi_1}[\log(\phi_0(x))] .$$

Since \( L(\cdot) = \log(\phi_0(\cdot)) \), (6) holds if and only if
$$\mathbb{E}_{x \sim \phi_1}[\log(\phi_1(x))] - \mathbb{E}_{x \sim \phi_0}[\log(\phi_1(x))] \geq 0 .$$

From (5) it follows that $\phi_0(x) = \phi_1(Q'(x - v))$, thus, by replacing the mathematical expectations with their integral expressions, (7) becomes
$$\int \log(\phi_1(x)) \phi_1(x) dx - \int \log(\phi_1(x)) \phi_1(Q'(x - v)) dx \geq 0$$

Let us define $y = Q'(x - v)$, then $x = Qy + v$ and $dx = |\det(Q)| dy = dy$, since $Q$ is orthogonal. Using this change of variables in the second summand of (8) we obtain
$$\int \log(\phi_1(x)) \phi_1(x) dx - \int \log(\phi_1(Qy + v)) \phi_1(y) dy \geq 0 .$$

Finally, defining $\phi_2(y) := \phi_1(Qy + v)$ turns (9) into
$$\int \log(\phi_1(x)) \phi_1(x) dx - \int \log(\phi_2(y)) \phi_1(y) dy \geq 0 .$$

which holds since the left-hand-side of (10) is $\text{KL}(\phi_1, \phi_2)$.

3.3 Detectability Loss

It is now possible to investigate the intrinsic challenge of change-detection problems when data dimension increases. In particular, we study how the change detectability (i.e., $\text{SNR}(\phi_0 \rightarrow \phi_1)$) varies when $d$ increases and changes $\phi_0 \rightarrow \phi_1$ preserve constant magnitude (i.e., $\text{sKL}(\phi_0, \phi_1) = \text{const}$). Unfortunately, since there are no general expressions for the variance of $L(\cdot)$, we have to assume a specific distribution for $\phi_0$ to carry out any analytical development. As a relevant example, we consider Gaussian random variables, which enable a simple expression of $L(\cdot)$. The following theorem demonstrates the detectability loss for Gaussian distributions, namely that $\text{SNR}(\phi_0 \rightarrow \phi_1)$ decays as $d$ increases.
**Theorem 1** Let $\phi_0 = \mathcal{N}(\mu_0, \Sigma_0)$ be a $d$-dimensional Gaussian pdf and $\phi_1 = \phi_0(Qx + v)$, where $Q \in \mathbb{R}^{d \times d}$ is orthogonal and $v \in \mathbb{R}^d$. Then, it holds

$$\text{SNR}(\phi_0 \to \phi_1) \leq \frac{C}{d}$$

(11)

where the constant $C$ depends only on $s_{KL}(\phi_0, \phi_1)$.

**Proof** Basic algebra leads to the following expression for $L(x)$ when $\phi_0 = \mathcal{N}(\mu_0, \Sigma_0)$:

$$L(x) = -\frac{1}{2} \log \left( (2\pi)^d \det(\Sigma_0) \right) - \frac{1}{2} (x - \mu_0)^T \Sigma_0^{-1} (x - \mu_0).$$

(12)

The first term in the right-hand-side of (12) is constant, while the second term is distributed as a chi-squared having $d$ degrees of freedom. Therefore,

$$\text{var}_{x \sim \phi_0} [L(x)] = \text{var}_{x \sim \phi_1} [L(x)] = \frac{d}{2}.$$ 

(13)

Then, from the definition of $\text{SNR}(\phi_0 \to \phi_1)$ in (11) and Proposition 1, it follows that

$$\text{SNR}(\phi_0 \to \phi_1) \leq \frac{s_{KL}(\phi_0, \phi_1)^2}{\text{var}[L(x)] + \text{var}[L(x)]} \leq \frac{s_{KL}(\phi_0, \phi_1)^2}{\text{var}[L(x)]} \leq \frac{s_{KL}(\phi_0, \phi_1)^2}{d/2} = \frac{C}{d}.$$ 

Theorem 1 shows detectability loss for Gaussian distributions. In fact, when $d$ increases and $s_{KL}(\phi_0, \phi_1)$ remains constant, $\text{SNR}(\phi_0 \to \phi_1)$ is upper-bounded by a function that monotonically decays as $1/d$. The decaying trend of $\text{SNR}(\phi_0 \to \phi_1)$ indicates that detecting changes becomes more difficult when $d$ increases. Moreover, the decaying rate does not depend on $s_{KL}(\phi_0, \phi_1)$, thus this problem equally affects all possible changes $\phi_0 \to \phi_1$ defined as in (1), disregarding their magnitude.

### 3.4 Discussion

First of all, let us remark that Theorem 1 implicates detectability loss only when $s_{KL}(\phi_0, \phi_1)$ is kept constant. Assuming constant change magnitude is necessary to correctly investigate the influence of the sole data dimension $d$ on the change detectability. In fact, when the change magnitude increases with $d$, changes might become even easier to detect as $d$ grows. This is what experiments in [23](Section 2.1) show, where outliers become easier to detect when $d$ increases. However, in that experiment, the change-detection problem becomes easier as $d$ increases, since each component of $x$ carries additional information about the change, thus increases $s_{KL}(\phi_0, \phi_1)$.

Even though similar techniques can be sometimes used for both change-detection and anomaly-detection, the two problems are intrinsically different, since the former aims at recognizing process changes, while the latter at identifying spurious data.
Detectability loss can be also proved when $\phi_0$ is non Gaussian, as far as its components are independent. In fact, if $\phi_0(x) = \prod_{i=0}^{d} \phi_0^{(i)}(x^{(i)})$, where $(\cdot)^{(i)}$ denotes either the marginal of a pdf or the component of a vector, it follows

$$\text{var}[L(x)] = \sum_{i=0}^{d} \text{var}_{x \sim \phi_0} \left[ \log \left( \phi_0^{(i)}(x^{(i)}) \right) \right],$$

(14)

since $\log(\phi_0^{(i)}(x^{(i)}))$ are independent. Clearly, (14) increases with $d$, since its summands are positive. Thus, also in this case, the upperbound of $\text{SNR}(\phi_0 \rightarrow \phi_1)$ decays with $d$ when $\text{sKL}(\phi_0, \phi_1)$ is kept constant.

Remarkably, detectability loss does not depend on how the change $\phi_0 \rightarrow \phi_1$ affects $X$. Our results hold, for instance, when either $\phi_0 \rightarrow \phi_1$ affects all the components of $X$ or some of them remain irrelevant for change-detection purposes. Moreover, detectability loss occurs independently of the specific change-detection method used on the log-likelihood (e.g. sequential analysis, or window comparison), as our results concern $\text{SNR}(\phi_0 \rightarrow \phi_1)$ only.

In the next section we show that detectability loss affects also real-world change-detection problems. To this purpose, we design a rigorous empirical analysis to show that the power of customary hypothesis tests actually decreases with $d$ when data are non Gaussian and possibly dependent.

4 Empirical Analysis

Our empirical analysis has been designed to address the following goals: i) showing that $\text{SNR}(\phi_0 \rightarrow \phi_1)$, which is the underpinning element of our theoretical result, is a suitable measure of change detectability. In particular, we show that the power of hypothesis tests able to detect both changes in mean and in variance of $L(\cdot)$ also decays. ii) Showing that detectability loss is not due to density-estimation problems, but it becomes a more serious issue when $\phi_0$ is estimated from training data. iii) Showing that detectability loss occurs also in Gaussian mixtures, and iv) showing that detectability loss occurs also on high-dimensional real-world datasets, which are far from being Gaussian or having independent components. We address the first two points in Section 4.1, while the third and fourth ones in Sections 4.2 and 4.3 respectively.

In our experiments, the change-detection performance is assessed by numerically computing the power of two customary hypothesis tests, namely the Lepage [19] and the one-sided $t$-test\(^3\) on data windows $W_P$ and $W_R$ which contains 500 data each. As we discussed in Section 3.2, the $t$-statistic on the log-likelihood is closely related to $\text{SNR}(\phi_0 \rightarrow \phi_1)$, while the Lepage is a nonparametric statistic that detects both location and scale changes\(^4\). To compute the power, we set $h$ to guarantee a significance level\(^5\) $\alpha = 0.05$. Following the procedure in Appendix,

---

\(^3\) We can assume that $\phi_0 \rightarrow \phi_1$ decreases the expectation of $L$ since $E_{x \sim \phi_0} \left[ \log (\phi_0(x)) \right] - E_{x \sim \phi_1} \left[ \log (\phi_0(x)) \right] \geq 0$ follows from (13).

\(^4\) The Lepage statistic is defined as the sum of the squares of the Mann-Whitney and Mood statistics, see also [20].

\(^5\) The value of $h$ for the Lepage test is given by the asymptotic approximation of the statistic in [19].
we synthetically introduce changes $\phi_0 \rightarrow \phi_1$ having $\text{sKL}(\phi_0, \phi_1) = 1$ which, in the univariate Gaussian case, corresponds to $\nu$ equals to the standard deviation of $\phi_0$.

4.1 Gaussian Datastreams

We generate Gaussian datastreams having dimension $d \in \{1, 2, 4, 8, 16, 32, 64, 128\}$ and, for each value of $d$, we prepare 10000 runs, with $\phi_0 = \mathcal{N}(\mu_0, \Sigma_0)$ and $\phi_1 = \mathcal{N}(\mu_1, \Sigma_1)$. The parameters $\mu_0 \in \mathbb{R}^d$ and $\Sigma_0 \in \mathbb{R}^{d \times d}$ have been randomly generated, while $\mu_1 \in \mathbb{R}^d$ and $\Sigma_1 \in \mathbb{R}^{d \times d}$ have been set to yield $\text{sKL}(\phi_0, \phi_1) = 1$ (see Appendix). In each run we generate 1000 samples: $\{x(t), t = 1, \ldots, 500\}$ from $\phi_0$, and $\{x(t), t = 501, \ldots, 1000\}$ from $\phi_1$. Then, we compute the datastream $L = \{L(x(t)), t = 1, \ldots, 1000\}$, and define $W_F = \{L(x(t)), t = 1, \ldots, 500\}$ and $W_R = \{L(x(t)), t = 501, \ldots, 1000\}$.

We repeat the same experiment replacing $\phi_0$ with its estimate $\hat{\phi}_0(x)$, where $\hat{\mu}_0$ and $\hat{\Sigma}_0$ are computed using the sample estimators over an additional training set $TR$ whose size grows linearly with $d$, i.e. $\#TR = 100 \cdot d$. We denote by $\tilde{L} = \{\tilde{L}(x(t)), t = 1, \ldots, 1000\}$ the sequence of estimated log-likelihood values. Finally, we repeat the whole experiments keeping $\#TR = 100$ for any value of $d$, and we denote by $\tilde{L}_{100}$ the corresponding sequence of log-likelihood values.

Figure 1(a) shows that the power of both the Lepage and one-sided $t$-test substantially decrease when $d$ increases. This result is coherent with our theoretical analysis of Section 3 and confirms that $\text{SNR}(\phi_0 \rightarrow \phi_1)$ is a suitable measure of change detectability. While it is not surprising that the power of the $t$-test decays, given its connection with the $\text{SNR}(\phi_0 \rightarrow \phi_1)$, it is remarkable that the power of the Lepage test also decays, as this fact indicates that it becomes more difficult to detect both changes in the mean and in the dispersion of $L$. The decaying power of both tests indicates that the corresponding test statistics decrease with $d$, which imply larger detection delays when using this statistics in sequential monitoring schemes.

Note that detectability loss is not due to density-estimation issues, but rather to the fact that the change-detection problem becomes intrinsically more challenging, as it occurs in the ideal case where $\phi_0$ is known (solid lines). When $L$ is computed from an estimated $\hat{\phi}_0$ (dashed and dotted lines), the problem becomes even more severe, and worsens when the number of training data does not grow with $d$ (dotted lines).

Figure 1(a) shows that the power of both the Lepage and $t$-test substantially decrease when $d$ increases. This result is coherent with our theoretical analysis of Section 3 and confirms that $\text{SNR}(\phi_0 \rightarrow \phi_1)$ is a suitable measure of change detectability. While it is not surprising that the power of the $t$-test decays, given its connection with the $\text{SNR}(\phi_0 \rightarrow \phi_1)$, it is remarkable that the power of the Lepage test also decays, indicating that changes become more difficult to be detected both in the mean and in the dispersion of $L$.

We interpret this result as a consequence of the intrinsic worsening of change detectability when $d$ increases. Moreover, detectability loss is not due to density-estimation issues, as it affects also ideal case where $\phi_0$ is known (solid lines). In the more realistic cases where $L$ is computed from an estimated $\hat{\phi}_0$ (dashed and dotted lines), the problem become more severe, in particular when the number of training data does not increase with $d$ (dotted lines).
4.2 Gaussian mixtures

We now consider $\phi_0$ and $\phi_1$ as Gaussian mixtures, to prove that detectability loss occurs also when datastreams are generated/approximated by more general distribution models. Mimicking the proof of Theorem 1, we show that when $d$ increases and $\text{KL}(\phi_0, \phi_1)$ is kept constant, the upper-bound of $\text{SNR}(\phi_0 \rightarrow \phi_1)$ decreases. To this purpose, it is enough to show that $\text{var} \left[ \mathcal{L}(x) \right]$ increases with $d$.

The pdf of a mixture of $k$ Gaussians is
\[\phi_0(x) = \sum_{i=1}^{k} \lambda_{0,i} \mathcal{N}(\mu_{0,i}, \Sigma_{0,i})(x) = \sum_{i=1}^{k} \frac{\lambda_{0,i}}{(2\pi)^{d/2} \det(\Sigma_{0,i})^{1/2}} e^{-\frac{1}{2} (x-\mu_{0,i})' \Sigma_{0,i}^{-1} (x-\mu_{0,i})},\]

where $\lambda_{0,i} > 0$ is the weight of the $i$-th Gaussian $\mathcal{N}(\mu_{0,i}, \Sigma_{0,i})$. Unfortunately, the log-likelihood $\mathcal{L}(x)$ of a Gaussian mixture does not admit an expression similar to (12) and two approximations are typically used to avoid severe numerical issues when $d \gg 1$.

The first approximation consists in considering only the Gaussian of the mixture yielding the largest likelihood, as in [3] i.e.,
\[\mathcal{L}_u(x) = -\frac{k \lambda_{0,i^*}}{2} \left( \log \left( (2\pi)^{d/2} \det(\Sigma_{0,i^*}) \right) + (x-\mu_{0,i^*})' \Sigma_{0,i^*}^{-1} (x-\mu_{0,i^*}) \right),\]

where $i^*$ denotes the index of the Gaussian yielding the largest likelihood. This approximation is known as the maximum likelihood approximation.

The second approximation is the Gaussian mixture approximation, where the log-likelihood is approximated by a single Gaussian with mean and covariance estimated from the data. This approximation is known as the mean squared error approximation.

These approximations are computationally efficient and widely used in practice, but they may not be as accurate as the exact log-likelihood.

\[\mathcal{L}_l(x) = -\frac{k \lambda_{0,i^*}}{2} \left( \log \left( (2\pi)^{d/2} \det(\Sigma_l) \right) + (x-\mu_l)' \Sigma_l^{-1} (x-\mu_l) \right),\]

where $\Sigma_l$ and $\mu_l$ are the estimated mean and covariance of the mixture.

4.2.1 Power and Variance

Fig. 1 (a) Power of the Lepage and one-sided t-test empirically computed on sequences generated as in Section 4.1. Detectability loss clearly emerges when the log-likelihood is computed using $\phi_0$ (denoted by $L$) or its estimates fitted on 100 · $d$ samples ($\hat{L}$) or from 100 samples ($\hat{L}_{100}$). (b) The sample variance of $\mathcal{L}_u(\cdot)$ [13] and $\mathcal{L}_l(\cdot)$ [14] computed as in Section 4.2. As in the Gaussian case, both these variances grow linearly with $d$ and similar results hold when using $\hat{\phi}_0$, which is estimate from 200 · $d$ training data.
Fig. 2 Detectability loss on the Particle Dataset (a) and Wine Dataset (b), approximated by a mixture of 2 and 4 Gaussians, respectively, using both \( \hat{L}_u \) and \( \hat{L}_l \). The powers of both Lepage and \( t \)-test decay, confirming the detectability loss. The tests based on \( \hat{L}_u \) outperform the corresponding ones based on \( \hat{L}_l \) because this latter approximation yields a larger variance, as can be seen in Fig 1(b).

where \( i^* \) is defined as

\[
  i^* = \arg \max_{i = 1, \ldots, k} \left( \frac{\lambda_{0,i}}{(2\pi)^d/2\det(\Sigma_{0,i})^{1/2}} e^{-\frac{1}{2}(x-\mu_{0,i})'\Sigma_{0,i}^{-1}(x-\mu_{0,i})} \right).
\]

The second approximation we consider is:

\[
  L_l(x) = -\frac{1}{2} \sum_{i=1}^{k} \lambda_{0,i} \left( \log \left( (2\pi)^d\det(\Sigma_{0,i}) \right) + (x - \mu_{0,i})'\Sigma_{0,i}^{-1}(x - \mu_{0,i}) \right),
\]

that is a lower bound of \( L(\cdot) \) due to the Jensen inequality.

We consider the same values of \( d \) as in Section 4.1 and, for each of these, we generate 1000 datastreams each containing 500 data drawn from the Gaussian mixture \( \phi_0 \). We assume \( k = 2 \) and \( \lambda_{0,1} = \lambda_{0,2} = 0.5 \), while the parameters \( \mu_{0,1}, \mu_{0,2}, \Sigma_{0,1}, \Sigma_{0,2} \) are randomly generated. We then compute the sample variance of both \( L_u \) and \( L_l \) over each datastream and report their average in Figure 1(b). As in Section 4.1 we repeat this experiment estimating \( \hat{\phi}_0 \) from a training set containing \( 200 \cdot d \) additional samples, then computing \( \hat{L}_u \) and \( \hat{L}_l \).

Figure 1(b) shows that the variances of \( L_u \) and \( L_l \) grow linearly with respect to \( d \), as in the Gaussian case. This result indicates that also in this case, where datastreams are generated by correlated and bimodal distributions, detectability loss occurs, since the SNR(\( \phi_0 \rightarrow \phi_1 \)) decreases when \( d \) increases. As in Section 4.1 we experienced the same trend when the log-likelihoods \( \hat{L}_u \) and \( \hat{L}_l \) are computed with respect to fitted models \( \hat{\phi}_0 \). We further observe that \( L_l \) exhibits a much larger variance than \( L_u \), thus we expect this to achieve lower change-detection performance than \( L_u \). Probably, this is why \( L_u \) was used in [3] instead of \( L_l \).
4.3 Real-World Data

To investigate detectability loss in real-world datasets, we design a change-detection problem on the Wine Quality Dataset \cite{24} and the MiniBooNE Particle Dataset \cite{25} from the UCI repository \cite{26}. The Wine dataset has 12 dimensions: 11 corresponding to numerical results of laboratory analysis (such as density, Ph, residual sugar), and one corresponding to a final grade (from 0 to 10) for each different wine. We consider the vectors of laboratory analysis of all white wines having a grade above 6, resulting in a 11-dimensional dataset containing 3258 data. The Particle dataset contains numerical measurements from a physical experiment designed to distinguish electron from muon neutrinos. Each sample has 50-dimensions and we considered only data from muon class, yielding 93108 data.

Since in either datasets $\phi_0$ is completely unknown, we need to estimate it for both introducing changes having constant magnitude and computing the log-likelihood. We adopt Gaussian mixtures and estimate $k$ by 5-fold cross validation over the whole datasets, obtaining $k = 4$ and $k = 2$ for Wine and Particle dataset respectively.

We process each dataset as follows. Let us denote by $D$ the dataset dimension and for each value of $d = 1, \ldots, D$ we consider only $d$ components of our dataset that are randomly selected. We then generate a $d$-dimensional training set of 200 $\cdot d$ samples and a test set of 1000 samples (datastream), which are extracted by a bootstrap procedure without replacement. The second half of the datastream is perturbed by the change $\phi_0 \rightarrow \phi_1$, which is defined by fitting at first $\phi_0$ on the whole $d$-dimensional dataset, and then computing $\phi_1$ according to the procedure in Appendix. Then, we estimate $\phi_0$ from the training set and we compute $T(\hat{W}_P, \hat{W}_R)$, where $\hat{W}_P, \hat{W}_R$ are defined as in Section 4.1. This procedure is repeated 5000 times to numerically compute the test power. Note that the number of Gaussians in both $\tilde{\phi}_0$ and $\hat{\phi}_0$ is the value of $k$ estimated from whole $D$-dimensional dataset, and that $\tilde{\phi}_0$ is by no means used for change-detection purposes.

Figure 2 reports the power of both Lepage and one-sided $t$-tests on the Particle dataset and Wine dataset, considering $\hat{L}_u$ \cite{16} and $\hat{L}_l$ \cite{17} as approximated expressions of the likelihoods. The power of both tests is monotonically decreasing, indicating an increasing difficulty in detecting a change among $\hat{W}_P$ and $\hat{W}_R$ when $d$ grows. This result is in agreement with the claim of Theorem 1 and the results shown in the previous sections. In contrast of Gaussian datastreams, the Lepage here turns to be more powerful than the $t$-test. This fact indicates that it is important to monitor also the dispersion of $\mathcal{L}(\cdot)$ in case of Gaussian mixture, where $\mathcal{L}(\cdot)$ can be multimodal. The decay of the power of the Lepage test also indicate that monitoring both expectation and dispersion of $\mathcal{L}(\cdot)$ does not prevent the detectability loss. Figure 2 indicates that $\hat{L}_u(\cdot)$ guarantees superior performance than $\hat{L}_f(\cdot)$ and this is a consequence of the lower variance of $\hat{L}_u(\cdot)$. This fact also underlines the importance of considering the variance of $\mathcal{L}(\cdot)$ in measures of change detectability, as in \cite{18}. We finally remark that have set a change magnitude (sKL($\phi_0, \phi_1$) = 1) that is quite customary in change-detection experiments, as in the univariate Gaussian case this corresponds to setting $v$ equals to the standard deviation of $\phi_0$. Therefore, since in our experiments the power of both tests is almost halved when $d \approx 10$, we can conclude that detectability loss is not only a Big-Data issue.
5 Conclusions

We provide the first rigorous study of the challenges that change-detection methods have to face when data dimension scales. Our theoretical and empirical analyses reveal that the popular approach of monitoring the log-likelihood of a multivariate datastream suffers detectability loss when data dimension increases. Remarkably, detectability loss is not a consequence of density-estimation errors – even though these further reduce detectability – but it rather refers to an intrinsic limitation of this change-detection approach. Our theoretical results demonstrate that detectability loss occurs independently on the specific statistical tool used to monitor the log-likelihood and does not depend on the number of input components affected by the change. Our empirical analysis, which is rigorously performed by keeping the change-magnitude constant when scaling data-dimension, confirms detectability loss also on real-world datastreams. Ongoing works concern extending this study to other change-detection approaches and to other families of distributions.

Appendix: Generating Changes of Constant Magnitude

Here we describe a procedure to select, given $\phi_0$, an orthogonal matrix $Q \in \mathbb{R}^{d \times d}$ and a vector $v \in \mathbb{R}^d$ such that $\phi_1 = \phi_0(Qx + v)$ guarantees $sKL(\phi_0, \phi_1) = 1$ in the case of Gaussian pdfs, and $sKL(\phi_0, \phi_1) \approx 1$ for arbitrary distributions. Extensions to different values of $sKL(\phi_0, \phi_1)$ are straightforward. Since $\phi_1(x) = \phi_0(Qx + v)$, we formulate the problem as generating at first a rotation matrix $Q$ such that

$$0 < sKL(\phi_0(\cdot), \phi_0(\cdot)) < 1$$

and then defining the translation vector $v$ to adjust $\phi_1$ such that $sKL(\phi_0, \phi_1)$ reaches (or approaches) 1.

We proceed as follows: we randomly define a rotation axis $r$, and a sequence of rotations matrices $\{Q_j\}$ around $r$, where the rotation angles monotonically decrease toward 0 (thus $Q_j$ tends to the identity matrix as $j \to \infty$). Then, we set $Q_j^*$ as the largest rotation yielding a $sKL < 1$, namely

$$j^* = \min\{j : sKL(\phi_0(\cdot), \phi_0(\cdot)) < 1\}. \tag{18}$$

When $\phi_0$ is continuous and bounded (as in case of Gaussian mixtures) it can be easily proved that such a $j^*$ exists.

In the case of Gaussian pdfs, when $\phi_0 = \mathcal{N}(\mu_0, \Sigma_0)$, $sKL(\phi_0, \phi_1)$ admits a closed-form expression:

$$sKL(\phi_0, \phi_1) = \frac{1}{2} \left[ v^\prime \Sigma_0^{-1} v + v^\prime Q \Sigma_0^{-1} Q^\prime v + 2v^\prime \Sigma_0^{-1} (I - Q) \mu_0 + 2v^\prime Q \Sigma_0^{-1} (Q^\prime - I) \mu_0 + \text{Tr}(Q^\prime \Sigma_0^{-1} Q \Sigma_0) + \text{Tr}(\Sigma_0^{-1} Q^\prime \Sigma_0 Q) - 2d + 2\mu_0^\prime (I - Q^\prime) \Sigma_0^{-1} (I - Q) \mu_0 \right], \tag{19}$$
and $\text{sKL}(\phi_0(\cdot), \phi_0(Q_j \cdot))$ can be exactly computed to solve (18). When there are no similar expressions for $\text{sKL}(\phi_0, \phi_1)$ this has to be computed via Monte Carlo simulations.

After having set the rotation matrix $Q$, we randomly generate a unit-vector $u$ as in [27] and determine a suitable translation along the line $v = \rho u$, where $\rho > 0$, to achieve $\text{sKL}(\phi_0, \phi_1) = 1$. Again, the closed-form expression (19) allows to directly compute the exact value of $\rho$ by substituting $v = \rho u$ into (19). This yields a quadratic equation in $\rho$, whose positive solution $\rho^*$ provides $v = \rho^* u$ that leads to $\text{sKL}(\phi_0, \phi_1) = 1$. When the are no analytical expressions for $\text{sKL}(\phi_0, \phi_1)$, we generate an increasing sequence $\{\rho_n\}_n$ such that $\rho_0 = 0$ and $\rho_n \to \infty$ as $n \to \infty$, and set

$$n^* = \max \{n : \text{sKL}(\phi_0(\cdot), \phi_0(Q \cdot + \rho_n u)) < 1\},$$

(20)

where $\text{sKL}(\phi_0(\cdot), \phi_0(Q \cdot + \rho_n u))$ is computed by Monte Carlo simulations. After having solved (20), we determine $\rho^*$ via linear interpolation of $[\rho_{n^*}, \rho_{n^*+1}]$ on the corresponding values of the skL. In this case, we can only guarantee $\text{sKL}(\phi_0, \phi_1) \approx 1$ with an accuracy that can be improved by increasing the resolution of $\{\rho_n\}_n$.
