CASE REPORT

Management of a complex pancreaticoduodenal lesion following a suicidal attempt with a crossbow

Abstract

Traumatic pancreaticoduodenal lesions are rare, often involve a challenging management, and have high rates of morbidity and mortality. A 43-year-old male patient committed a suicidal attempt by shooting an arrow with a crossbow into his upper abdomen. He was successfully treated with a cautious multidisciplinary approach. Crossbow lesions demonstrate low kinetics. Sharp tips of arrows result in localized damage, likely to involve several organs. Pancreatic lesions are of particular interest because of their difficult surgery. Surgical exploration and drainage can allow an efficient management of pancreatic penetrating lesions, even in the presence of a complete pancreatic duct disruption.

INTRODUCTION

Most abdominal traumas result from motor vehicle accident, fall, interpersonal violence and only rarely from suicidal attempt [1, 2]. The radiological assessment includes a focused assessment with sonography in trauma (FAST), and, in stable patients, an abdominal computer tomography (CT). Signs of penetrating injury, the presence of free fluid/free air, and clinical signs of guarding or shock are classical indications for a surgical exploration.

We report the case of a suicidal attempt using a crossbow directed to the epigastric area, a rare and intriguing vector of injury nowadays. It implied multidisciplinary management, especially related to the presence of a complete disruption of the pancreatic duct. Only few cases of crossbow suicidal attempts were reported throughout the world, most of which are from forensic studies, as such injuries are most often fatal [1]. Beyond the description of the case, we discuss the management of complex pancreatic lesions.

CASE PRESENTATION

A 43-year-old male patient, with no relevant past medical history, has been admitted to the emergency department after having attempted suicide by shooting a crossbow arrow at his abdomen. He was haemodynamically stable, and fully conscious. The arrow penetrated the epigastric area, without an exit wound, and was left untouched by the emergency team (Fig. 1).
A contrast-enhanced CT and 3D reconstructions showed the projectile entering medially at the epigastrium, passing through segment IVb of the liver, progressing to the first part of the duodenum, pancreatic head and finally stopped by the left facies articularis of L4–L5 vertebrae (Fig. 2A and B). In addition, haematomas were present in the lesser sac, and in the duodenal loop with a shift of the mesenteric vessels to the left. At emergency laparotomy, there was a small amount of free blood in the abdominal cavity. Trustworthy CT findings appeared as a valuable help to surgical procedures. A tactical cholecystectomy was performed, and a cholangiogram demonstrated the absence of bile duct lesion. The arrow was removed by splitting the edge of segment IV of the liver. It was subsequently extracted from the vertebrae with the help of neurosurgeons, and tributaries of a lumbar artery were clipped for haemostasis. Anterior and posterior wounds of the duodenum were closed with interrupted polydioxanone sutures. The gastroenterologist performed an endoscopic retrograde cholangiopancreatography, which showed a complete disruption of the distal part of the Wirsung duct, and a stenting was thus not performed. Prolene interrupted sutures were applied to the anterior and posterior surface lesions of the pancreatic head, and two drains were left locally. A jejunostomy was placed for post-operative enteral feeding.

Post-operative follow-up was complicated by the occurrence of a pancreatic fistula (Fig. 3). The patient was kept on octreotide in order to minimize the exocrine pancreatic secretion. A control CT at 4 weeks showed resolution of the fistula and abdominal drains could be removed. Besides, vertebral damage was minimal and presented a favourable outcome. Finally, psychiatric evaluation concluded to schizophrenia.

DISCUSSION

Crossbows are potentially lethal weapons used for sport and hunting. In Switzerland, they can be freely purchased for private use, but are strictly prohibited in the public areas and for hunting. Crossbows have become popular and are increasingly reported in criminal acts [3, 4]. Carets and arrows usually induce very localized lesions, compared to those caused by firearms. They typically have lower kinetic energy and are fitted with a sharp end, which desiccates body tissues. On the opposite, bullets impact the body surface with a high energy, and generate tearing. Finally, the shaft of the arrow may compress surrounding wounded tissue [3].

The first step is to assess haemodynamics. The primary radiological abdominal evaluation is based on FAST echography, with or without chest and abdomen X-rays. In haemodynamically stable patients, CT has become the gold standard for early evaluation of abdominal blunt and penetrating trauma [1, 2].

Such a CT assessment is of special interest in injuries caused by arrows, such as the one of our patient. Imaging allows a precise visualization of the arrow trajectory, and enables to build detailed 3D reconstructions, which is not the case with bullet injuries.

Pancreatic trauma occurs in <5% of patients with abdominal trauma. It is complex to manage, due both to the presence of frequently associated lesions, and to its anatomical site and the nature of its parenchyma. Pancreatic trauma is associated with a high mortality and morbidity. Determining factors are the presence of associated injuries to nearby organs, vessels or bile duct, the presence of shock and time to surgery [5, 6]. Complications include fistulas, infections, pseudocysts and abscesses [7, 8]. As in the present case, combined pancreatic-duodenal injuries (PDIs) are infrequent complications, 80% of
which are caused by penetrating mechanisms, and associated with high mortality rates of 18–30% [9].

Whipple’s procedure has first been described in 1965 for PDI. Some advocate that it should still be performed in selected patients with trauma [9, 10]. We argue that it involves high complication rates in the emergency setting, and that therefore it should only be performed as a last resort option. Most authors nowadays support rapid, simple and damage-control surgery, showing better outcomes than complex procedures. Van der Wilden et al. showed that less invasive management was non-inferior to Whipple’s procedure in a retrospective analysis of 77 patients with severe PDI [9, 10]. Our patient illustrates the management of severe PDI with simple repair and drainage.

Current recommendations for stable patients with blunt abdominal trauma are to assess injuries with a CT scan. In the case of a crossbow injury, the arrow left in the place allows precise 3D-CT reconstruction, and provides support to the medical and surgical teams. The management of multiple intra-abdominal lesions requires a multidisciplinary approach in order to elaborate the best treatment plan. Emergency Whipple’s procedure remains uncommon, in favour of less invasive procedures. Simple repair, lavage and external drainage are frequently appropriate alternative options, even in the presence of a complete pancreatic duct disruption.
