Tunneling Qubit Operation on a Protected Josephson Junction Array

Zhi Yin, Sheng-Wen Li, and Yi-Xin Chen
Zhejiang Institute of Modern Physics, Zhejiang University, Hangzhou 310027, China

We propose a complete quantum computation process on a topologically protected Josephson junction array system, originally proposed by Ioffe and Feigel’man [Phys. Rev. B 66, 224503 (2002)]. Logical qubits for computation are encoded in the punctured array. The number of qubits is determined by the number of holes. The topological degeneracy is lightly shifted by tuning the flux along specific paths. We show how to perform both single-qubit and basic quantum-gate operations in this system, especially the controlled-NOT (CNOT) gate.

I. INTRODUCTION

Quantum algorithm shows us a tempting future to conquer some problems that are hard to solve using classical computers[1], such as, factorizing large numbers[2], searching in a large database[3], and so on. However, the physical realization of a quantum computer turns out to be a really difficult work. The greatest obstacle is the decoherence of system induced by unavoidable coupling with the surrounding environment[4]. Since quantum devices work in a microscopic scale, their interactions with the environment become fatal to the quantum coherence of the system. Someting has to be done to increase the decoherence time so as to complete enough operations within so short a period of time.

Therefore, error correcting code (ECC) is needed[1]. With the help of ECC a small error rate can be tolerated. However, since the necessary error-rate threshold still lies far beyond the present available technology, other methods to fight against error should be considered. One promising method is topological quantum computation (TQC) [5][6][7].

Topological order[8][9][10][11] is a new kind of quantum order. Although the mechanism of topological order is not quite clear, we can find the following features in a system in topological order:

1. The degeneracy of the ground state closely relates to the topology of the physical system (usually 2-dimensional).

2. The system is immune to local perturbation and this property can be used to protect qubits.

3. Excited quasiparticles may obey anyon statistics (Abelian or non-Abelian)[8].

With its great advantages, non-Abelian TQC[7] attracts us the most. In a non-Abelian topological phase, not only can the encoded qubits be protected, but also the operation process can be protected intrinsically through the braiding of non-Abelian anyons. Much has been discussed about the Fibonacci anyons that can be used for TQC directly in Quantum Hall Effect. However it is hard to control anyons in real quantum Hall systems. Besides, Kitaev proposed a spin-1/2 honeycomb model[12], which seems achievable, followed by some different possible physical implementations[13][14][15][16][17]. The work in Ref.[17] proposed a more sophisticated method for the anyon detection process. Unfortunately, the non-Abelian anyons that emerged in this model do not act well enough to complete the full braiding operation of TQC. Attractively, B. Doucot, et al. gave a complete description of the rhombus Josephson junction array (JJA) with Abelian and non-Abelian gauge theories[18]. However, this is too complex for implementation.

Because of all these difficulties we are facing, we will turn to the Abelian topological phase in which qubits can be protected as well. Recently, Kou showed how to do computations in the toric code model by using the tunneling effect theoretically[19][20][21]. However, the original toric code model calls for four-body interaction, which is hard to implement in real systems.

The Josephson junction seems to one of the candidates to implement a realistic quantum computation[22][23][24][25]. Ioffe and Feigel’man proposed a hexagonal Josephson junction lattice that showed some topological protecting properties which can be used as quantum memory[25].

Based on their work, we propose a complete TQC scheme in this article. We focus on encoding logical qubits in the array and the construction of quantum gates. Similar to the method of Kou, we also show how to implement fundamental quantum gates, especially the CNOT gate.

The article is organized as follows. In Sec. II, we introduce Ioffe and Feigel’man’s model in detail. In Sec. III, we study the ground-state behavior. Topological degeneracy is used to encode qubits in the array. In Sec. IV we show how to manipulate the qubits to complete basic quantum gate operation. Finally, we draw summary in Sec. V.
II. HEXAGONAL JOSEPHSON LATTICE

To describe the computation process we first introduce the model proposed by Ioffe and Feigel’man [22] in this section. In this work, They showed that the array system exhibits some topological protecting properties and thus can be used as quantum memory. We discuss how to do computations based on their work in the next section. Now we recount some basic properties of their model in detail first. These properties are essential for the construction of computation gates. For the convenience of the computation we talk about, we make a small modification with the boundary and discuss further the quasi-particle excitation, especially the vortex, which agrees, in essence, with the original model.

First, we give the basic building element and explain how it works. Then we show how the array is arranged and give the dynamics of the system. Finally, we talk about the topological degeneracy of the ground space and the low-lying excitations.

A. Basic rhombus

As shown in Fig.1 the basic building block is a rhombus made of a four-junction superconducting loop placed in a magnetic field. The flux through the rhombus is \( \Phi_0/2 \), where \( \Phi_0 = \hbar/2e \) is the flux quanta. We require that all the Josephson junctions are the same and work in the “phase regime”, that is, \( E_J \gg E_C \), where \( E_J = (h/2e)I_0 \) and \( E_C = e^2/2C \).

This system, as is much discussed in the literature, forms a simple two-level “flux qubit” (or persistent-current qubit) [23][26]. In the following, we briefly explain how the qubit system emerges.

We denote the phase of the superconductor islands with \( \psi_i \). The Josephson system is described with the Lagrangian

\[
\mathcal{L} = \sum_{ij} \frac{\hbar^2}{16E_C} (\dot{\psi}_i - \dot{\psi}_j)^2 + E_J \cos(\psi_i - \psi_j - a_{ij}),
\]

where \( a_{ij} = \frac{2e}{\Phi_0} \oint_{i} \vec{A} \cdot \vec{d} \vec{l} \). The quantity in the cosine term is the gauge-invariant phase difference across each junction.

Here, we make an approximation that three of the junctions have the same phase difference. As all phase differences should sum up to \( 2\pi \Phi_{ext}/\Phi_0 \), we get

\[
U = 4E_J - 3E_J \cos \frac{\Delta \phi}{2} + E_J \cos \frac{3\Delta \phi}{2}.
\]

where \( \Delta \phi \) indicates the phase difference between the two far ends of the rhombus. Neglecting the kinetic part, this energy has two equivalent classical minima at \( \Delta \phi = \pm \pi/2 \) (as shown in Fig1), that is, the phase difference across each junction is \( \pm \pi/4 \). So the two classical ground states correspond to states in which there are both clockwise and counterclockwise supercurrents in the loop. This is the reason why we call it a persistent-current qubit. We denote the two states as \( | \uparrow \rangle \) and \( | \downarrow \rangle \). Quantum fluctuation makes the electron tunnel between the two classical states in the wells and that splits the degenerate ground states. The low-energy configuration can be regarded as a two-level qubit system. The effective Hamiltonian is

\[
H = \tilde{t} \sigma_x,
\]

where \( \tilde{t} \sim \sqrt{E_J E_C} e^{-S_0} \), and \( S_0 \) is the classical action taking the path between the two minima. The value of tunneling energy is estimated regarding the potential as quadratic.

Let us see what happens when the condition is slightly changed from the ideal. Notice that the dynamics require that the flux through the rhombus is exactly half a flux quanta. If the external flux is a bit different from the ideal value, \( \Phi_0/2 + \delta \Phi \), we add a first order change to the potential,

\[
\tilde{U} = 4E_J - 3E_J \cos \frac{\Delta \phi}{2} - E_J \cos(\pi + 2\pi \frac{\delta \Phi}{\Phi_0} - \frac{3\Delta \phi}{2})
\]

\[
\approx U + E_J \sin \frac{3\Delta \phi}{2} \cdot 2\pi \frac{\delta \Phi}{\Phi_0}.
\]

As a result of the slight change of the flux, the two minima of the double well are no longer degenerate but separated by a gap \( \Delta E = 2\sqrt{2\pi E_J \delta \Phi}/\Phi_0 \). Then the effective Hamiltonian is \( \tilde{H} = \tilde{t} \sigma_x + \frac{1}{2} \Delta E \sigma_z \).

This is important for operations. We can control the evolution of the system by adjusting the flux through the rhombus. Below, in the Josephson array building from the basic rhombi, logical qubits are encoded for computation. Some gate operations are done just by the method of tuning the flux of the rhombi along specific paths.

B. Array

Now we have got the bricks we need. In this part we show how to build the Josephson array system.

The basic rhombi are arranged as shown in Fig2. For simplicity, a rhombus is indicated by a short line in the
The product takes the rhombi on the hexagon loops.

Because of the existence of the constraint, the rhombi embedded in the array can no longer behave as in Eq. (3), which does not commute with the constraint. The simplest dynamics compatible with constraint contain flips of three adjacent rhombi, $Q_{abc} = \sigma^z_{ab} \sigma^z_{bc} \sigma^z_{ca}$, such that two rhombi flip at the same time in the corresponding three hexagons. This gives the main contribution to the Hamiltonian of the system

$$\hat{H}_0 = -r \sum_{abc} \hat{Q}_{abc}. \quad (6)$$

Here, $r \sim \sqrt{E_J E_C} \exp(-3S_0)$ is estimated to be analogous to $t$ in the last section. The action in the exponential term is three times of that of a single rhombus because of the simultaneous flip of the three rhombi.

C. Boundary

Now we talk about the boundary. We should treat it carefully. The boundary here is arranged a bit differently from Ioffe’s original model. Different boundary conditions of the toric code have been discussed in detail [27]. In the system considered here, similarly, the boundary is arranged more like the “rough edge”.

Here, we arrange the boundary rhombi in such a way that they behave like those in the bulk, as described by Eq. (6). Each rhombus on the boundary still stays close to the other two. A superconductor line connects the unattached rhombi at the outer and inner boundary (like the blue line in Fig. 2).

The geometry of the polygon loops on the boundary should be carefully treated. A boundary loop has $m$ rhombi, usually three or four. We want to maintain the dynamics and constraint of the form as before, that is, two rhombi must flip at one time. So the flux embedded should be consistent with the sum of the phase differences of the $m$ rhombi, i.e., $(n_b + \frac{m}{2})\Phi_0$, where $n_b$ is an integer. Then the Hamiltonian Eq. (6) is still kept for the rhombi on the boundary.

We complete the construction of the Josephson array and give the low-energy dynamics. In the following section, we will discuss the properties of the ground-state space and excitations in detail.

D. Topological degeneracy, charge and vortex excitation

In this section, we discuss the properties of the ground space and excitations. The topological degeneracy of the ground space can be used to encode logical qubits for computation. We show two kinds of quasiparticles in the system, charge and vortex. We can operate qubits by controlling their motion in the array.

First, let us find the ground state of the system. Ignoring the constraint, we can easily get the ground state of
Hamiltonian (6) as $|O\rangle = \prod |+\rangle = \prod(|\uparrow\rangle + |\downarrow\rangle)/\sqrt{2}$. Of course, it is illegal and incompatible with the constraint. We can project it into the physical space with the help of an operator

$$\hat{P} = \prod_{a} \frac{1 + \hat{P}_{a}}{\sqrt{2}}.$$  \hfill (7)

$|g\rangle = \hat{P}|O\rangle$ is a ground state of the system, but not the only one.

To find all the ground states, we can turn to the help of a path operator

$$\hat{T}_{\gamma_{k}} = \prod_{|ab\rangle}^{\langle \gamma_{k}} \sigma_{ab}^{x}.$$  \hfill (8)

where $\gamma_{k}$ takes the big (red) loop in Fig[2]. Notice that all the $\hat{T}_{\gamma_{k}}$ with the paths homotopic with $\gamma_{k}$ are equivalent. Also it is easy to check that $\hat{T}_{\gamma_{k}}$ commutes with both $H$ and $\hat{P}_{a}$. So obviously $\hat{T}_{\gamma_{k}}|g\rangle$ is another ground state of $H$. Noting that $\hat{T}_{\gamma_{k}}^{2} = 1$, we can construct all the ground states

$$|G\rangle = \prod_{\gamma_{k}} 1 + \hat{T}_{\gamma_{k}} \frac{\sqrt{2}}{\hat{P}|O\rangle}.$$  \hfill (9)

Here, the product contains all the $K$ “basic loops” (i.e., loops around each single hole).

Note that in the representation above, $\hat{T}_{\gamma_{k}}|G\rangle = \pm|G\rangle$. So we can interpret $\hat{T}_{\gamma_{k}}$ as the operator measuring the “spin” direction of the kth hole. We will utilize this physical meaning of $\hat{T}_{\gamma_{k}}$ for encoding in the next section.

Now we find the whole ground space of the array system with $K$ holes. The dimension of the ground space is just $2^{K}$. It is interesting that the degeneracy correlates with the topology of the system. This is why it is called topological degeneracy. We can encode $K$ qubit in this space and do computations in it.

Based on the knowledge of the ground space, let us study the low-lying excitations of the system. An open string product of $\sigma^{z}$, which is compatible with the constraint, excites two “charges” at the two ends of the string. With the help of the anti-commutation relation with the Hamiltonian, after a simple algebra computation, we can deduce that the energy of each single “charge” is $2\pi r$ above the ground.

Unfortunately, a string product of $\sigma^{z}$ is not allowed by the constraint, which is different from the case in toric code model[3]. To get another type of excitation, we should break the constraint Eq. (5) and contemplate the problem from the original Lagrangian of the array. Approximately, we only keep the degree of freedom of the superconductor islands at the two ends of the rhombi (i.e., at the vertices of the hexagons). Correspondingly, we use the modified potential Eq. (2). Then the Lagrangian of the array is

$$\mathcal{L} = \sum_{(ij)} \frac{\hbar^{2}}{16EC}(\psi_{i} - \psi_{j})^{2} + 3E_{J} \cos \frac{\Delta\psi_{ij}}{2} - E_{J} \cos \frac{3\Delta\psi_{ij}}{2},$$  \hfill (10)

where $\Delta\psi_{ij} = \psi_{i} - \psi_{j} - \int_{c} \vec{A} \cdot \vec{l}$. Taking the continuum limit, the Josephson array system can be mapped to a Type-II superconductor[28]. A vortex solution exists in the system, taking one flux quanta. The energy of a single vortex is

$$E_{g} = \frac{\Phi_{0}^{2}}{4\pi\mu_{0}\lambda^{2}} \ln \frac{\lambda}{\xi}.$$  \hfill (11)

Here, $\lambda^{2} = \Phi_{0}^{2}/9\pi^{2}\mu_{0}E_{J}$, and $\xi$ is the length between the two centers of the hexagons.

Vortices stay at the hexagons where the constraint is broken. The dynamics there are changed correspondingly. There is one kind of dynamic that interests us most, the single flip of a rhombus. To get this kind of dynamics, we carefully change the flux of two adjacent hexagons to integer multiples of $\Phi_{0}$. Two vortices appear and stay here. Single flip happens only at the rhombus between the two hexagons. Since the other rhombus stay close to the hexagons that satisfy the constraint, the single flip is still not allowed. This is also the reason why we must change the flux of two adjacent hexagons, but not one or two separated hexagons. If we change the flux of only one hexagon, we still cannot get the single flip because it is forbidden by the adjacent hexagon.

Now we can add a $\sigma^{z}$ term to $\mathcal{H}_{0}$ with the amplitude $\hat{t}$ at the rhombus between the two adjacent vortices. Or rather, we can interpret it in such a way that two vortices with each energy $E_{g}$ are excited by a $\sigma^{z}$ operation. This term is important for operations that we will discuss later. So we have got two types of quasi-particle excitations in the array.

III. PROTECTED QUBIT AND COMPUTATION

After all the discussions about the properties of the array we focus, in this section, on the computation process. It was mentioned in Ref. [25] that motion of quasiparticles along topologically non-trivial paths changes the state. We care about how to achieve it. In this section, we show how to encode logical qubits in the array, and propose an exact method to operate qubits in lab.

However, first we give a short review of stabilizer code formalism. In fact, this system can be regarded as stabilizer code. Then we show how the topological degenerated ground space is protected from local noise. Logical qubits are encoded in the “holes”. The spin directions of holes can be used to denote the state of the $K$ logical qubits. Finally, we show how to implement the single qubit and multi-qubits operations.
A. Stabilizer code

Stabilizer code is developed as a general theory of quantum error-correction code[1]. In this formalism, $N$ physical qubits are used to encode $K$ logical qubits ($N > K$). Certain types of errors can be detected and corrected so that the reliability of quantum computation is greatly improved.

First, we define the Pauli group $G_N$ on $N$ qubits as

$$G_N = \{i^k (\sigma_1^a)^{a_1} (\sigma_2^a)^{b_1}, \ldots, (\sigma_N^a)^{a_N} (\sigma_N^b)^{b_N}\},$$

where $k, a_i, b_i$ are integers. $G_N$ contains all the $N$-body Pauli operators with coefficients $\pm 1, \pm i$. Note that any two elements in the Pauli group either commute or anti-commute with each other.

A subgroup $S$ of $G_N$ is called a stabilizer group if there exists a nontrivial space $V_S$ stabilized by $S$,

$$V_S = \{|\psi\rangle \ g(\psi) = |\psi\rangle, \ \forall g \in S\}. \quad (13)$$

It can be proved that $V_S$ is $2^N$-dimensional if the group $S$ has $N - K$ independent generators. We denote the stabilizer group as $S = \{g_1, g_2, \ldots, g_{N-K}\}$, where $g_i$ is one of the $N - K$ generators of the group. The elements in $S$ are called stabilizer operators, or just stabilizers.

$K$ logical qubits are encoded in the stabilized space $V_S$. To correct errors, we should first notice that the effects of errors can be represented by the one-body elements in the Pauli group $G_N$, because errors are usually local. When no error happens, after measuring all the stabilizers in $S$ (just measuring all the $N - K$ generators is ok.), all results are 1. Assume one error, denoted by $E \in G_N - S$, happens, so that the original computation state $|\psi\rangle \in V_S$ is changed to $E|\psi\rangle$. If $E$ anti-commutes with at least one stabilizer in $S$, e.g., $g$, the measurement of $g$ gives the result $-1$, then we know the error type and we can correct it by corresponding operation. However, there may exist some elements in $G_N - S$ that also commute with all the elements in $G_N$. This type of errors can not be detected or corrected.

The basis of logical qubits should be written out for computation. We can always find $K$ operators $Z_i$ from $G_N - S$ such that $g_1, \ldots, g_{N-K}, Z_1, \ldots, Z_K$ form an independent operator set. $Z_i$ plays the role of a logical operator $\sigma_z$. The logical computational basis $|x_1, x_2 \ldots x_K\rangle_L$ is actually the state stabilized by the group

$$\langle g_1, \ldots, g_{N-K}, (-1)^{x_1} Z_1, \ldots, (-1)^{x_K} Z_K \rangle. \quad (14)$$

The logical $X_i$ can be also found from $G_N - S$ satisfying:

1. $[X_i, X_j] = 0$ and
2. $\{X_i, Z_j\} = 2\delta_{ij}$.

We emphasize here that the logical operator set $\{Z_i\}$ is not unique. Also, we did not limit $Z_i$ to be of some certain form such as a product of several $\sigma^z$. It can be a mixed product of $\sigma^z$ and $\sigma^x$, or even a product that contains only $\sigma^x$. The only condition required is that $g_1, \ldots, g_{N-K}, Z_1, \ldots, Z_K$ form an independent operator set. For example, suppose we find a set $\{\tilde{Z}_i\}$ that satisfies the condition and $\{\tilde{X}_i\}$ is the set of corresponding logical flipping operators, it is easy to check that $\{g_1, \ldots, g_{N-K}, \tilde{X}_1, \ldots, \tilde{X}_K\}$ is also an independent set. So the status of logical sets $\{Z_i\}$ and $\{X_i\}$ are the same, and their roles can be exchanged.

B. Logical qubit encoding

In this section, we show how to encode logical qubit in the topological protected array. As an example, the toric code is a kind of stabilizer code. The computation is done in the ground space of $H_{TC} = -g \sum A_i - h \sum B_p$, where $A_i$ and $B_p$ are the star and plaquette operators. The ground space is stabilized by the operators $\{A_i, B_p\}$. The loop products of $\sigma^x$ and $\sigma^z$ along two directions give rise to the logical gate $Z_1, Z_2, X_1$ and $X_2$.

But toric code model only encodes two logical qubits. If we want to encode more qubits, we have to implement a much too complex boundary condition for more genus. In our system with puncture topology, we can see that encoding is much easier.

We can write down the stabilizers in our considering model, $\{\hat{P}_i\}$ and $\{Q_{abc}\}$. The physical ground space satisfying $\hat{P}_a|\psi\rangle = Q_{abc}|\psi\rangle = |\psi\rangle$ constitutes the protected code space. But this is not enough. Now we have to find the logical operators $\{\tilde{Z}_i\}$ and $\{\tilde{X}_i\}$. In an array with $K$ holes, we can see that the product of $\sigma^x$ around the $k$th hole (i.e., $\hat{T}_k$ mentioned earlier), actually plays the role of logical operator $\tilde{Z}_k$. We have mentioned that eigenvalues $\pm 1$ of $\tilde{Z}_k$ can be regarded as the spin values of the $k$th hole. We can also find the logical operator $\tilde{X}_k$ as the product of $\sigma^z$ along the path from the outer boundary to the inner of the $k$th hole (The yellow lines connecting the right hole to the outer boundary in Fig.3). $\tilde{X}_k$ flips the spin of the $k$th hole to the opposite direction.

It may feel strange that we take the loop product of $\sigma^x$ as logical $\tilde{Z}$ while taking the string product of $\sigma^z$ as logical $\tilde{X}$. We should notice that the string product of $\sigma^x$ is not allowed by constraints at the two ends of the string. On the other hand, although we can exchange the roles of $\tilde{X}$ and $\tilde{Z}$ as mentioned earlier, the representation we chose here has a better physical meaning as “spin”.

Therefore, we denote the logical computation basis by the spin directions of the holes, like $\uparrow_1 \uparrow_2 \ldots \uparrow_K \ldots$. The corresponding single qubit operations are $\tilde{Z}_k$ and $\tilde{X}_k$, formally. We emphasize again that all the homotopic paths are equivalent.

Now we show why the code space is protected against local noise. We assume that the noise can be treated as local perturbations on the rhombus, $\sigma_k^z$. To consider the perturbation effect of the first order, we compute the matrix element $\langle G_\alpha | \sigma^z | G_\beta \rangle$. $\{\langle G_\alpha |, | G_\beta \rangle, \ldots\}$ is a set of orthogonal basis of the ground space $V_G$, as discussed
in the last section. There must exist at least one $\sigma^x$ that anti-commutes with $V$, so $\sigma^x |G_\beta\rangle$ is driven outside $V_G$ and $\langle G_\alpha |\sigma^x|G_\beta\rangle$ is zero. Only perturbations of an order higher than $N$ take effect, such that $N$ Pauli operators form a topologically nontrivial path across different boundaries, or form a loop embedding at least one hole. When $N$ is large enough, the system can be well protected and this is the reason why it is called topologically protected.

When it is cooled to a low enough temperature, the system arrives at the protected ground space automatically. The computation is well protected from local noises. However, proper perturbations can drive quasi-particles tunnel through nontrivial paths, and this can be used to construct quantum gates. We will do computations by this method in the following part.

### C. Single qubit operation

We showed how the computation basis for logical qubits are represented. Now let us see how to implement quantum gate operations in this system. From the discussion of the system previously, we know that quasi-particles are excited by Pauli operators. The product operators of $\sigma^x$ and $\sigma^z$ along topologically non-trivial paths change the state of the system. So we get a more physical picture that the transmission of both charge and vortex changes the state. This can be used for operation in this section.

To complete the qubit gates operation, we use a method similar to Kou’s [21]. We change the external magnetic field. Effectively, the ground space behaves as a pseudo-spin system. We can see that it just drives the quasi-particles to tunnel through different sectors.

As an example, we slightly tune the flux of the rhombi along a path from the $k$th hole to the outer boundary. According to the previous discussion, perturbations of the $\sigma^z$ form appear in the single-rhombus Hamiltonian, and this is allowed by the constraint. So we get the Hamiltonian

$$\hat{H} = \hat{H}_0 + \frac{\Delta E}{2} \sum_{\text{path}} \sigma^z = \hat{H}_0 + H'\tag{15}$$

Confined in the degenerate ground space, the main part gives identity with an energy coefficient. The effect of perturbation appears in the $(N - 1)$th order. $N$ is the number of rhombi along the path. One can get the energy splitting [21]

$$\delta \epsilon = \sum_j \langle \uparrow k | H' \left( \frac{1}{E_0 - \mathcal{H}_0} H' \right)^j | \uparrow k \rangle = \frac{(\Delta E/2)^N}{(-4g)^{N-1}}. \tag{16}$$

where $E_0$ is the ground energy of $\mathcal{H}_0$. Each $H'$ contributes one single $\sigma^z$. Only the term that contains a complete string product of $\sigma^z$ connecting both the inner and outer boundaries takes effect as $X_k$ (remember that in the representation we use here, products of $\sigma^x$ behave as $X$ not $Z$!), while others vanish. So we get the effective Hamiltonian of the array as $\mathcal{H}_\text{eff} = \delta \epsilon \tilde{X}_k$.

In this process, a charge tunnels across the array from the $k$th hole to the outer boundary. Degenerate states split just as in the case in the double-well of a single rhombus.

Similarly, we want to get an effective Hamiltonian like $\mathcal{H}_\text{eff} \sim \tilde{Z}_k$ by adding perturbations of the form such as $\sum \sigma^x$. However, as mentioned before, this is not allowed by the constraint under ideal condition. Something more should be done. We have talked about the vortex excitation in the last section. To achieve this purpose, we carefully change the flux of the hexagons along the loop around the $k$th hole (as shown in Fig. 2) to be integer multiples of $\Phi_0$. The constraint is broken, and the dynamics of the corresponding hexagon changes. The single flip of a rhombus is allowed. So we get the desired perturbation as

$$\hat{H} = \hat{H}_0 + \tilde{t} \sum_{\text{loop}} \sigma^z \tag{17}$$

where $\tilde{t}$ takes the value in Eq. (3). Two vortices emerge. One is transmitted around the $k$th hole, and then annihilates the other one. This process gives the $\tilde{Z}$ term. Similar to Eq. (16), we get the energy splitting

$$\delta E = \sum_j \langle \uparrow k | H' \left( \frac{1}{E_0 - \mathcal{H}_0} H' \right)^j | \uparrow k \rangle = \frac{\tilde{t}^N}{(-2E_g)^{N-1}}. \tag{18}$$

So we have got $\mathcal{H}_\text{eff} = \delta E \tilde{Z}_k$.

As we known, any single-qubit rotation can be written as

$$U(\theta, \phi, \gamma) = e^{-i\gamma \tilde{Z}} e^{-i\phi \tilde{X}} e^{-i\theta \tilde{Z}}. \tag{19}$$

We have got both $\mathcal{H}_\text{eff} = \delta E \tilde{Z}_k$ and $\mathcal{H}_\text{eff} = \delta E \tilde{X}_k$, then we can get any single qubit gate, at least in principle [29].

We can tune the corresponding flux of rhombi or hexagons and get the effective Hamiltonian we need, carefully control the evolution time of the system (that is to tune the parameters $\gamma, \phi, \theta$ above), then we can construct any single qubit gate we want.
In the last part, we saw that any single qubit gate can be constructed. In the this section, we show that in this array multi-qubit operations are also easy to realize on any two qubits.

When we change the flux of the rhombi on the line connecting two holes (see the yellow line in Fig[4], similarly, the states of the corresponding two qubits are flipped at the same time, and this gives $\hat{X}_m \otimes \hat{X}_n$ term in the Hamiltonian. By using the perturbation approach, the amplitude is

$$\alpha = \sum_j \langle \uparrow_m \downarrow_n | H'(\frac{1}{E_0 - \hat{H}_0})^j | \downarrow_m \uparrow_n \rangle = (\frac{\Delta E}{2})^N \frac{(-4r)^{N-1}}{(-4)^{N-1}}. \tag{20}$$

Here, $H' = \frac{\Delta E}{2} \sum \sigma^x$, and the summation contains all the rhombi on yellow line. We get a effective Hamiltonian $\hat{H}_{eff}^{\alpha} = \alpha \hat{X}_m \otimes \hat{X}_n$.

Analogously, we can get another type of operation. We can tune the flux of the hexagons along the loop around two holes to integer multiples of $\Phi_0$. This gives a perturbation $H' = i \sum \sigma^x$. The amplitude is

$$\beta = \sum_j \langle \uparrow_m \downarrow_n | H'(\frac{1}{E_0 - \hat{H}_0})^j | \downarrow_m \uparrow_n \rangle = \frac{i^N}{(-2E_g)^{N-1}}. \tag{21}$$

Then we get the effective Hamiltonian $\hat{H}_{eff}^\beta = \beta \hat{Z}_m \otimes \hat{Z}_n$.

The most important thing we are concerned with is to construct CNOT operation, because CNOT gate together with arbitrary single qubit rotation gate gives rise to a universal quantum computation. This is also realizable in this array.

First, we should construct another effective Hamiltonian. We tune the flux in such a way that a vortex is transmitted around the $n$th hole, and a charge is transmitted from the $r$th hole to the outer boundary at the same time. The effective Hamiltonian contains contributions of three parts, $\hat{H}_{eff}^{\gamma} = \gamma_1 \hat{Z}_m + \gamma_2 \hat{X}_n + \gamma_3 \hat{Z}_m \otimes \hat{X}_n$. $\gamma_1, \gamma_2$ and $\gamma_3 = \gamma_1 \gamma_2$ are evaluated in the same way with $\delta E$ and $\delta E$ in the last section.

A CNOT gate can be constructed with the help of $\hat{H}_{eff}^{\gamma}, \hat{H}_{eff}^{\alpha}$ and $\hat{H}_{eff}^{\beta}$. We can let $\hat{H}_{eff}^{\gamma}$ evolve for $t_1 = \frac{\pi}{2\gamma_1}$. Then we should change the external magnetic field to construct $\hat{H}_{eff}^{\alpha}$ and let the system evolve for $t_2 = \frac{\pi}{4\gamma_1} - t_1$.

Finally, we construct $\hat{H}_{eff}^{\beta}$ and let the system evolve for $t_3 = \frac{\pi}{2\gamma_1} - t_1$. Now we get the CNOT operation with an external global phase $e^{-i\pi/4}$, which is negligible.

$$e^{-i\pi/4}U_{\text{CNOT}} = e^{-i\hat{R}_{\gamma}^{\pm} t_1} e^{-i\hat{R}_{\alpha}^{\pm} t_2} e^{-i\hat{R}_{\beta}^{\pm} t_3} \tag{22}$$

IV. SUMMARY

In summary, we propose a TQC scheme with protected qubits in a JJA system, and we indicate how to perform qubit encoding, single qubit operation, and multi-qubit operation. Especially, we show the way to implement the CNOT quantum gate operation which is a key element in quantum computation.

The scheme we propose here can be realized in real JJA system since the technology of the Josephson junction is developing rapidly. Considering the convenience of realizability and scalability of our system, the dimension of ground space is related to the number of punctures on the array. The logic qubit encoding here is in a protected space so that our system is topologically protected from noise. Besides, specific quasiparticles are driven by proper perturbation transmitted along topologically non-trivial path. This makes small splittings happen. We give the effective Hamiltonian under different condition corresponding to various splitting situations and this can be used to do quantum computation.

In practice, the evolution time is controlled by an electric pulse with specific length, but usually we cannot produce pulses with arbitrarily continuous length. But we can still complete arbitrary single qubit operation approximately with a limited set of gates, so we just need several specific pulses.
