ABSTRACT

Background. There is limited information available on the use of assisted peritoneal dialysis (PD) over time and the impact of economic incentives on its utilization. The aim of this study was to describe the trends in assisted PD utilization and the type of assistance provided. We wanted to estimate if an economic incentive implemented in 2011 in France was associated with an increase in the utilization of nurse-assisted PD.

Methods. This retrospective, multicentre study, based on data from the French Language Peritoneal Dialysis Registry, analysed 11 987 patients who initiated PD in France between 1 January 2006 and 31 December 2015. Adjusted Cox regression with robust variance was used to examine the initiation of assisted PD, both nurse-assisted and family-assisted, accounting for the nonlinear impact of the PD starting time.

Results. There were 6149 (51%) incident patients on assisted PD, 5052 (82%) on nurse-assisted PD and 1097 (18%) on family-assisted PD over the study period. In the adjusted analysis, calendar time was associated with the assisted PD rate: it declined from 2008 until 2013 before flattening out and then it increased after 2014. Nurse-assisted PD utilization increased significantly after 2012, whereas family-assisted PD utilization decreased linearly over time (prevalence ratio = 0.94, 95% confidence interval 0.92–0.97).

Conclusions. The assisted PD rate decreased until 2013, mainly because of a decline in family-assisted PD. The uptake in nurse-assisted PD observed from 2013 reflects the effect of an economic incentive adopted in late 2011 to increase PD utilization.

Keywords: assisted peritoneal dialysis, chronic kidney disease, economic incentives, longitudinal trends, peritoneal dialysis
INTRODUCTION
The initiation of dialysis can be emotionally challenging for patients and families; presenting patients with choices of dialysis modality may ease the burden of stress and anxiety. Older age, comorbidities, physical disabilities and psychosocial problems act as barriers to home dialysis [1–5]. Compared with in-centre haemodialysis (HD), peritoneal dialysis (PD) offers several advantages, such as the avoidance of transport to and from the dialysis unit, avoidance of difficulties in creating vascular access and haemodynamic instability during the HD session [3, 6–8]. By overcoming some of the conditions that act as a barrier to self-care PD [4, 9], assistance can improve the accessibility of home dialysis and thus favour quality of life in elderly patients [3, 9–11].

Home assistance programmes have been implemented in several countries in recent decades. Depending on the country, the assistance can be provided by a healthcare technician, a community nurse, and a trained family member or partner [12]. With the first programmes being implemented in the 1980s, France has one of the longest experiences of assisted PD [13, 14]. Nurse-assisted PD is fully covered by the French healthcare insurance. Notably, assisted PD remains cheaper than in-centre HD, even after the additional costs for nurse assistance [15]. Assisted PD allows patients to choose their PD modality (e.g. automatic peritoneal dialysis (APD) or continuous ambulatory PD (CAPD)) and the type of assistance (nurse or a family-assisted PD). According to the French Language Peritoneal Dialysis Registry (RDPLF), > 50% of incident patients treated by PD from 1995 to 2006 were considered unable to perform self-care PD and needed assistance. The assistance was mainly provided by a private nurse (45% of patients) or to a lesser extent by a family member (7%). In the elderly population, > 80% needed assistance [16].

Strategic economic incentives to increase home dialysis by altering remuneration for these therapies are being introduced [17]. Despite these incentives and the many advantages home dialysis can offer, PD use has been declining in recent decades [18], while the total number of dialysis patients has increased [19, 20]. It is unclear whether this decline is linked to an ageing population, which may be associated with limited use of home therapy unless assistance is provided. With the population in CKD growing older and frailer, we could anticipate an increase in the utilization of nurse-assisted PD. According to the French Language Peritoneal Dialysis Registry (RDPLF), > 50% of incident patients treated by PD from 1995 to 2006 were considered unable to perform self-care PD and needed assistance. The assistance was mainly provided by a private nurse (45%) or to a lesser extent by a family member (7%). In the elderly population, > 80% needed assistance [16].

Explanatory variable
The main explanatory variable was the time, or PD start year, between 1 January 2006 and 31 December 2015. For the secondary objective, the explanatory variable was the time period following the implementation of the coverage of nurse-assisted PD in nursing home (the number of years between 2011 and the year of PD start).

Statistical analysis
Continuous variables were described by the median (first and third quartile), and categorical variables were described by frequencies and percentages. Regression splines were used to explore the functional form of the length of time from the inclusion date until the end of the inclusion period. Transformation of the continuous time variable to a categorical variable was performed based on the aspect of the graph of the functional form of the predictor.

When the proportion of the event of interest is > 10%, the odds ratio (OR) overestimates the prevalence ratio (PR). Alternative methods have been described in the literature for the analysis of binary outcomes in longitudinal studies, including using the PR instead of the OR. The Cox model with robust variance is valid for estimating the PR [26]. To explore the association between the time variable and the events of interest in the complete cohort, PRs and 95% confidence intervals (CIs) were calculated using a Cox regression model with robust variance. As recommended, in the Cox model, a constant risk period equal to one was assigned to every patient in the cohort [26].
To evaluate the association between the time variable and CAPD utilization, analyses were restricted to the cohort of patients on assisted PD and subsequently to the nurse-assisted PD and family-assisted PD subgroups.

Cumulative incidence curves were drawn for each possible PD outcome (death, transfer to HD and renal transplantation) and for peritonitis events. Technique survival and peritonitis rates according to the type of assistance were compared using the Logrank test. Conditional probabilities for the event of interest were estimated at specific time points.

A bivariable analysis was performed to estimate the association between each variable and the event of interest. The time variable was included a priori in the multivariate analysis; otherwise, variables were included in the model based on the results of the change in the estimate procedure with a cut-off value of 10%. Interactions between time and the other covariates were tested in the multivariate models.

Missing data were <5%, enabling us to use a complete case analysis. Analyses were performed with R 3.4.3 (R Foundation for Statistical Computing, Vienna Austria, including the survival package).

RESULTS
Patient characteristics

Of the 11,987 incident patients on PD included in the study, 6149 (51%) patients were on assisted PD: 5052 (82%) were on nurse-assisted PD and 1097 (18%) were on family-assisted PD. The number of patients starting PD per year is displayed in Figure 1. The median (interquartile range (IQR)) time on PD was 19.3 months (8.4–34.5 months). Compared with self-care PD patients, those on assisted PD were older, more frequently diabetic and had more comorbidities. Patient characteristics according to the type of assistance are described in Table 1. Incident patients’ age and CCI by year of PD start are described in Table 2.

Association between calendar time and the rate of assisted PD utilization

In the multivariable analysis, time was associated with the assisted PD rate, whether included in the regression model as a regression spline (Figure 2) or as a categorical variable (Table 3).

The year 2013 was the time point with the lowest rate of assisted and nurse-assisted PD utilization and was chosen as the reference class in the corresponding modelling. There was a linear relationship between time and family-assisted PD utilization; thus, the PD start year was defined as a linear variable in this model.

Compared with 2013, starting PD in 2006, 2007, 2008, 2009, 2010, 2012 or 2015 was strongly associated with the utilization of assisted PD. Nurse-assisted PD utilization increased significantly after 2012, whereas family-assisted PD utilization decreased linearly over time (PR = 0.94, 95% CI 0.92–0.97; Table 3).

Age, gender, diabetes, modified CCI, a suboptimal start, underlying nephropathy, renal replacement therapy before PD initiation and centre experience were associated with assisted PD (Table 3). There were no significant interactions between PD start year and the other covariates.

Association between calendar time and the rate of CAPD utilization in the assisted PD, nurse-assisted PD and family-assisted PD subgroups

Based on the shape of the regression spline, the PD start year for this part of the analysis was transformed into a categorical variable composed of three classes: 2006–10, 2010–12 (reference class) and 2012–15. In the unadjusted and adjusted analyses, the PD start year was associated with an increased rate of CAPD utilization, whether included in the Cox regression model as a regression spline (data not shown) or as a categorical explanatory variable (Table 4).

Starting PD in 2012, 2013, 2014 or 2015 was strongly associated with an increased rate of CAPD utilization (PR = 1.16, 95% CI 1.08–1.23). The PR change over time followed a similar pattern in nurse-assisted PD patients (PR = 1.13, 95% CI 1.05–1.21) and family-assisted PD patients (PR = 1.24, 95% CI 1.03–1.49; Table 4).

Age, gender, modified CCI, a suboptimal start, therapy before PD initiation and centre experience were associated with CAPD initiation (Table 4). There were no significant interactions between PD start year and the other covariates.

Technique survival and peritonitis rates according to the type of assistance

The median (IQR) PD duration for the complete cohort was 16.9 months (7.38–30.9). There were 10,942 (91%) PD failures during the study period, including 4252 (35%) deaths and 3648 (30%) transfers to HD. Furthermore, 2262 (19%) patients had a renal transplantation. According to the type of assistance, the median (IQR) PD duration was 16.6 months (6.1–31.5) and 15.5 months (7.1–31.3) for patients on nurse- and family-assistance, respectively. Technique survival rates did not differ according to the type of assistance (P = 0.57). Conditional probabilities using the cumulative incidence method for the events are provided in Table 5.

In the complete cohort, there were 4421 (37%) episodes of peritonitis, with a median (IQR) time to peritonitis of 8.9 months (3.1–19.6). There were 1826 (36%) episodes of peritonitis in the nurse-assistance group and 406 (37%) in the family-assistance group. Median (IQR) time to peritonitis were of 8.8 months (2.8–19.8) and 8.5 months (2.2–20.3), respectively. Patients on nurse assistance tended to have less peritonitis compared with patients on family assistance even though the results were not significant (P = 0.08). The cumulative incidence of peritonitis at
DISCUSSION

Assisted PD programmes are available in different countries around the world, with differences from one country to another [12]. To our knowledge, the trend in the utilization of assisted PD among incident PD patients over time has not yet been documented at a national level. We hereby provide a description of the utilization of assisted PD over a decade in a country where assisted PD has been available for >30 years and is fully covered by healthcare insurance. The high exhaustivity of the RDPLF makes it a reliable database [22, 23].

With the CKD population growing older and frailer, it would be anticipated that the use of assisted PD should increase over the years. However, our results show a different pattern; there was a decline in the rate of assisted PD until 2013, while the total number of dialysed patients continued to increase [19]. The decline in the assisted PD rate was mainly attributed to a linear decline in family-assisted PD utilization.

In contrast, after 2013, there was an increased utilization of nurse-assisted PD over time (Figure 2). Surprisingly, patients’ age and comorbidities remained stable during the study period (Table 2), leading to the hypothesis that the potential rate of patients who needed assistance did not decrease during the decade.

The linear decline observed in family-assisted PD utilization could be explained by several factors. First, there was a modification in the state of health of caregivers. In a French survey published in 2008, 48% of the caregivers were suffering from chronic disease, and 29% declared that they were suffering from anxiety and stress [27]. Life expectancy has been rising in France over the past decade; however, while life expectancy without disability remains stable (64.5 years old for women and 63.4 years old for men) [28], the number of people suffering from...
chronic disease has been constantly rising [29, 30]. The number of caregivers in France is estimated to be 11 million, of which almost 35% are aged >60 years old, and 74% feel that being a caregiver has an impact on their own health [31, 32].

Secondly, social deprivation in the elderly (>75 years old) has been increasing steadily; in 2014, 27% of elderly individuals were considered to live with social deprivation compared with 16% in 2010. The population with social deprivation is now composed of more than a quarter of the people aged >75 years. This increase has been associated with a combination of several factors: an increase in the proportion of elderly people with disabilities, a relative decline in associative practices and a loosening in family relationships [33].

Finally, the proportion of patients on PD with a CCI >7 did not decrease over time (Table 2), reflecting frailty and dependency, which could influence the caregiver’s burden. The increase in caregiver burden, often associated with a reduction in psychological health, has been previously reported [34, 35]. It has recently been shown that a high proportion of patients will observe a decline in functional status in the first 6 months after initiating dialysis [36]. In a study from our team, compared with autonomous PD patients, patients with nurse assistance had a lower risk of transfer to HD, while those with family assistance had a similar risk of transfer to HD. This finding could be partly explained by the usefulness of nurse assistance to reduce the burden of PD for both patients and their families [11, 37, 38]. As the caregiver burden increased over time, family assistance declined. Interventions will be needed in the future to remove this burden and facilitate the task of caregivers.

On the other hand, the recent uptake in nurse-assisted PD could be explained by economic incentives and/or better coverage of home dialysis.

Economic incentives to increase home dialysis by altering remuneration for these therapies are being introduced in some countries. A recent workshop concluded that economic incentives were effective at increasing the use of home dialysis [17]. However, the time until an impact on incident home dialysis numbers can be observed remains unclear.

In France, nursing homes receive a financial budget from the healthcare insurance that covers collective medical costs (human resources and medical devices). The nursing time dedicated to each patient is based on a standard medical care evaluation. However, patients on PD might need assistance up to four times a day, 7 days a week, increasing the need for human resources. Nurse-assisted PD is fully covered by the healthcare insurance in France; however, prior to 2011, no fee was paid if the patient resided in a nursing home [39]. According to Dratwa et al., the evaluated additional costs generated by nurse-assistance were ~23 400 €/patient/year for CAPD (four exchanges per day) and 18 200 €/patient/year for APD [39]. Most nursing homes were not willing to pay for these additional charges. As a consequence, most end-stage renal disease patients on PD did not have access to nursing homes or had to change modality to HD to be accepted. Thanks to an economic

FIGURE 2: PR of assisted PD initiation over time. Change in the PR of assisted PD initiation over time. Solid lines represent the rates of receiving assisted PD at any point during follow-up, by the year PD was initiated, when compared with 2006 (expressed as a PR). The analysis was adjusted for age, gender, ethnicity and underlying nephropathy using a Cox regression model with robust variance (95% CI shown by dashed lines). The assisted PD PR over the study period was not linear. The PR for assisted PD was defined as PD performed at the patient’s home with the help of a community nurse or a family member (a), for nurse-assisted PD only (b) and family-assisted PD only (c).
incentive implemented in November 2011, the fees generated by nurse assistance are now fully covered, even if the patients reside in a nursing home [21]. That means that private nurses are paid, since 2011, to perform PD in the nursing home. We believe that this incentive translated into an increase in nurse-assisted PD from 2013.

The funding models for dialysis can also impact the use of home dialysis. In the USA, the prospective payment system, a bundle payment, for the US Medicare End-Stage Renal Disease Programme was launched in January 2011. It reduced financial disincentives for facility use of home therapies. PD payment was set to be equivalent to in-centre HD treatment. The number of patients on PD increased by 15% between 2011 and 2013 [17, 40]. There was an increasing tendency of patients on PD to be treated in facilities with less PD experience, without any changes in mortality rates. This finding suggests a link between the funding model and the modality distribution [17, 40, 41].

As shown by the adjusted Cox model, the relative use of CAPD increased over the study period, notably between 2012 and 2015 (PR = 1.16, 95% CI 1.08–1.23). This increase was noted in both nurse- (PR = 1.13, 95% CI 1.05–1.21) and family-assisted PD (PR = 1.24, 95% CI 1.03–1.49). In a recent study from our team, technique survival and peritonitis-free survival were similar between CAPD and APD in assisted PD patients [42]. In addition, a study of incident self-PD patients demonstrated a similar quality of life in both modalities, underlining the importance of the patient’s choice [43]. Both modalities should be offered to assisted PD patients; however, in view of the CAPD rate, one may wonder if APD is considered by the PD team to be equally suitable as CAPD for assisted patients with physical disabilities or cognitive dysfunctions. Moreover, nursing homes are often reluctant to deal with cyclers during the night because of the small number of caregivers available at night in those facilities.

Older age, diabetes, a higher CCI and underlying nephropathy were also associated with an increased probability of assisted PD initiation, likely a reflection of increased comorbidity, frailty and dependency. Similar findings have been described previously [11, 25]. It has been demonstrated that functional

*According to the spline regression, PD start year was modelled as a linear variable (per year).
Technique survival and peritonitis rates in our population were similar to previous studies [11, 45]. Both types of assistance have been associated with a lower risk for technique failure or transplantation, but a higher risk for death as the patients were older and frailer [11]. In older patients, nurse assistance has been associated with a lower risk for peritonitis [45]. Our findings are in line with previous studies, demonstrating the sustainability of assisted PD.

The use of PD remains low in France, with <10% of patients utilizing this modality [19]. Over time, patients starting dialysis seem to be older and more likely to be diabetic and have cardiovascular or respiratory comorbidities [19]. The use of assisted PD could reflect a nephrologist preference for this modality for older and frailer patients.

Our study has limitations; by nature, the observational design cannot lead to conclusions regarding causality. We have shown results on the use of assisted PD compared with all PD utilization; however, this study was not designed to show an effect on overall PD utilization as this would require data on all renal replacement therapy patients. Although the use of assistance can change over time, only the assistance at dialysis start was used for the analysis. Because of the particularity of the coverage in France, assisted PD utilization might differ from other countries, which could limit the generalizability of our results. However, we believe that the results of our study could help centres anticipate what could possibly happen in the future when implementing an assisted PD programme.

Our study also shows that, due to a decline in family assistance, assisted PD currently relies mainly on nurse assistance. It has been demonstrated that widespread adoption of assisted

### Table 5. Cumulative incidence of PD outcomes at specific times points with the cumulative incidence function estimate

| Event per type of assistance | 6 months | 12 months | 18 months | 24 months |
|-----------------------------|----------|-----------|-----------|-----------|
| All patients                |          |           |           |           |
| Death                       | 8.7      | 17.2      | 26.4      | 37.7      |
| Transfer to HD              | 9        | 16.6      | 25.5      | 34.5      |
| Renal transplantation       | 3.3      | 9.8       | 16.6      | 24.5      |
| Nurse-assisted PD patients  |          |           |           |           |
| Death                       | 15.9     | 30.2      | 45.9      | 64.2      |
| Transfer to HD              | 8.7      | 13.9      | 20.3      | 26.4      |
| Renal transplantation       | 0.5      | 1.8       | 2.6       |           |
| Family-assisted PD patients |          |           |           |           |
| Death                       | 13.6     | 28.8      | 41.4      | 60.9      |
| Transfer to HD              | 8.7      | 17.2      | 27.7      | 34.1      |
| Renal transplantation       | 0.8      | 3.3       | 6.1       | 7.6       |

Results are expressed as percentages.
PD services would significantly increase PD initiation [46]. Although there are added costs to nurse-assisted PD, a Netherlands study demonstrated that it is a cost-effective option [47] in elderly patients. To further develop PD utilization in developed countries, nurse assistance should be promoted. We believe that assisted PD programmes, notably nurse assistance, should be implemented in every PD centre to increase PD utilization [48]. Alternatively, economic incentives to the patient’s family could be considered, to convince relatives to participate in PD care. Such incentives do not exist in France currently.

In conclusion, this study shows that in France, the assisted PD rate decreased until 2013, mainly because of the decline of family assistance. The uptake in nurse-assisted PD observed from 2013 probably reflects the effect of an economic incentive adopted in late 2011 to increase PD utilization for end-stage renal disease patients in nursing homes.

ACKNOWLEDGEMENTS

The authors thank the participating centres of the French Language Peritoneal Dialysis Registry.
