(Dated: September 23, 2020)

We propose a new quantum numerical scheme to control the dynamics of a quantum walker in a two-dimensional space-time grid. More specifically, we show how, introducing a quantum memory for each of the spatial grid, this result can be achieved simply by acting on the initial state of the whole system, and therefore can be exactly controlled once for all. As example we prove analytically how to encode in the initial state any arbitrary walker’s mean trajectory and variance. This brings significantly closer the possibility of implementing dynamically interesting physics models on medium term quantum devices, and introduces a new direction in simulating aspects of quantum field theories (QFTs), notably on curved manifold.

Quantum control is to use to drive a quantum state to a desired target or outcome. Several theoretical and experimental approaches to model controlled wave packets and their application are very useful to pave the way for future simulation or quantum calculation schemes [14,15]. In many of these, the physical system to be controlled is driven by an external potential, which needs to be controlled all along the experience, until the target is achieved. Although in this work we do not claim to offer a general theory of quantum control, we provide a new approach in which the control scheme is encoded once and for all into its initial state. The main protagonist here is not a generic quantum system, but a quantum encoded once and for all. As example we prove analytically how to encode in the initial state any arbitrary quantum walks (QW) in discrete time [2,16,31]. What may seem like a particular choice, in reality offers great potential given the recognised versatility of this simple system. In fact, QW are a universal computational model [11,21] that spans models of a large spectrum of physical and biological phenomena, relevant both for fundamental science and for applications. Applications include search algorithms [3,17,25,26] and graph isomorphism algorithms [9] to modeling and simulating quantum [3,13,18] and classical dynamics [10,12]. These models have sparked various theoretical investigations covering areas in mathematics, computer science, quantum information and statistical mechanics and have been defined in any physical dimensions [22,23] and over several topologies [1,4,28]. QW appear in multiple variants and can be defined on arbitrary graphs. Essentially, QW have two registers: one for its position on the graph and the other is its internal state, often called coin state. It propagates on the graph, conditioned by its internal state, similarly to the classical case, where at each step we flip a coin to determine the direction of the walker. The essential difference is that in the quantum case, the walker propagates in superposition on the graph in various directions starting from a node. This feature allows the quantum walker to explore the graph quadratically faster a classical one, property that make it very useful to design, e.g., efficient search algorithms. However, we don’t know many way to control the quantum walker evolution. For instance we can choose the initial condition and the evolution operator to tune the walker’s variance \( \sigma(t) = a f(t) \), where \( a \) is a real prefactor and \( f(t) \) is typically a linear function of \( t \). However, once these are fixed at the initial time, both \( f \) and \( a \) remain the same all along the evolution, unless we don’t allow the evolution operator to change in an in-homogeneous way at each time-step, which may be very costly. How can we control the walker’s dynamics at our will without having to change the evolution operator? Would it be possible to control, having only the initial condition, the variance or its average trajectory? In this manuscript we argue that, at the price of introducing a quantum memory, the answer is positive. Quantum walks with memory have already been studied and come in several variants [19,20]. As example, these modified quantum walks may have extra coins to record the walkers latest path, as in [24,27]. Here, the idea is to define an additional quantum memory for each site in the grid, with which the walker interacts throughout the evolution. Surprisingly, we will prove that the initial condition of the whole system, memory + walker, is sufficient to control, e.g., the variance of the walker for all times.

The manuscript is organised as follows: in the first section we provide the definition of the model; then, in the second section, we will prove analytically and numerically how to control the variance and the mean trajectory of a quantum walker, solely via the initial condition of the whole system and in the third and last section, we discuss and conclude.

THE MODEL

Formally, the simplest but non trivial QW is defined on a Hilbert space which has position and velocity (internal ”spin” state) components. The position Hilbert space \( X \) is the set of states \( \{x\} \) where \( x \in \mathbb{Z}_N \), and the velocity Hilbert space is \( V = \mathbb{C}^2 \), for which we may choose some orthonormal basis labeled \( \{|v^\rangle, |v^+\rangle\} \). Denote the QW Hilbert space by \( \mathcal{H} \),

\[
\mathcal{H} = X \otimes V.
\]
The overall state of the walker at time $t \in \mathbb{N}$ may thus be written
\[ \Psi(t) = \sum_x \psi_x^+(t) |x| \otimes |v^+\rangle + \psi_x^-(t) |x| \otimes |v^-\rangle, \]
where the scalar field $\psi_x^+$ (resp. $\psi_x^-$) gives, at every position $x \in \mathbb{Z}_X$, the amplitude of the particle being there and about to move right (resp. left). We can write an amplitude vector at time $t$ and position $x$ over the ordered basis of the coin space $\{|v^+, v^-\}$,
\[ \psi_x(t) = \begin{pmatrix} \psi_x^+(t) \\ \psi_x^-(t) \end{pmatrix}. \]
Let $W$ be the evolution of the QW at each time step,
\[ \psi_x(t+1) = W \psi_x(t). \]

$W$ is composed of a coin operator $C$, an arbitrary element of $U(2)$, acting on the velocity space, e.g.,
\[ C = \begin{pmatrix} \cos \theta & i \sin \theta \\ i \sin \theta & \cos \theta \end{pmatrix}, \]
followed by a shift operator $S$
\[ S \psi_x(t) = \begin{pmatrix} \psi_{x-1}^+(t) \\ \psi_{x+1}^-(t) \end{pmatrix}, \tag{1} \]
with the overall evolution being
\[ W = S(\text{Id}_X \otimes C), \]
where $\text{Id}_X$ is the identity operator on the position Hilbert space.

Quantum memory Now, let us consider that at each site $x$ of the grid we have a supplementary qubit $|n_x\rangle \in \mathcal{M}^2 = \mathbb{C}^2$. This extended Hilbert space, as proved in [30, 31], may be used as a quantum memory to keep track of the past of the walker. Notice that the size of the Hilbert space now seems to be growing exponentially. However, according to [29] this is not going to be an issue for infinite lattices as the Hilbert space lies now in $\mathcal{M}^2 \otimes \text{Id}_X \otimes \mathbb{C}^2$.

The whole state (QW + quantum memory) lies now in $X \otimes V \otimes \mathcal{M}^2 \otimes \mathcal{M}^2$. Indeed, one of the main motivation of this history dependent QW is to build a truly self-avoiding walker: One knows that the walker moves towards the left or towards the right according to the internal coin state; thus, in order to avoid sites already visited by the walker, one conditions the coin state on the neighbor memory states, which eventually recorded previous presence of the walker.

The coin operator $C$ of the previous section is replaced by a different operator $Q$ that acts on the joint velocity-memory space : $V \otimes \mathcal{H}_{M^{t-1}} \otimes \mathcal{H}_{M^{t+1}}$ - whose basis is the set of $|v^\alpha \beta_\delta\rangle$, $\alpha = \{+,-\}$, $|\beta\rangle$ and $|\delta\rangle$ being the memory qubits located respectively at the positions $(x-1)$ and $(x+1)$ - so that the memory qubits adjacent to the position $x$ of the walker are involved:
\[ Q = \{ |v^+1\rangle \langle v^00\} + |v^00\rangle \langle v^-0\} + |v^-0\rangle \langle v^+1\} + |v^+1\rangle \langle v^-0\} + |v^-1\rangle \langle v^00\} + |v^00\rangle \langle v^-1\} + |v^-1\rangle \langle v^+0\} + |v^+0\rangle \langle v^-1\}. \]

Finally, the shift operator still acts on the joint velocity-position space in the standard manner, as defined in Eq. (1), and trivially on the memory space. Altogether the global evolution is:
\[ \Psi(t+1) = G \Psi(t) \]
\[ G = SQ \]

CONTROL THE WALKER’S DYNAMICS

To simplify our analysis, we choose a localized set of initial conditions
\[ \Psi(0) = |0\rangle \langle v^-| \left( \bigotimes_{x=-1}^{x=0} \begin{pmatrix} 1 \\ x - \left\lfloor \frac{x}{2} \right\rfloor \end{pmatrix} \right) \left( \bigotimes_{x=0}^{x=1} |0\rangle \right) \]
(2)

which is equivalent to requiring that all those sites with a nonzero internal state have all quantum memories to their right set to $|0\rangle$.

By looking at the single walker subspace, the recurrence relations for each amplitude, detailed in Appendix , read :
\[ \psi_x^-(t+1) = A_{-x} \psi_{x+1}^-(t) \]
\[ \psi_x^+(t+1) = \psi_{x-1}^+(t) + B_{-x+2} \psi_{x-1}^-(t) \]
and given Eq. (2) we prove the following theorem :

Theorem .1. The left-moving and right-moving amplitudes $\psi_x^\pm(t)$, solutions of the linear set of Eqs. (2), reads:
\[ \psi_x^-(t) = \begin{cases} \prod_{i=1}^t A_i & \text{if } x = -t \\ 0 & \text{else} \end{cases} \]
and
\[ \psi_x^+(t) = \begin{cases} 0 & \text{if } |x| > t \\ 0 & \text{if } x = -t \\ B_{t-x+1} \prod_{j=1}^{t-x} A_j & \text{if } x - t \text{ is odd} \end{cases} \]

Proof. We can prove the above theorem by induction. Indeed, let us first compute $\psi_{x+1}^- (t + 1)$, we may discern two cases:
\[ \bullet x \neq -(t+1) \Rightarrow \psi_{x+1}^-(t + 1) = 0 \]
\[ \bullet x = -(t+1) \Rightarrow \psi_{x+1}^-(t + 1) = 0 \Rightarrow \psi_x^-(t + 1) = 0 \]
Once we know the analytical expression of the probability density of the walker, which reads:

\[
p(x, t) = a \delta(x - v t)
\]

where, the above probability density is vanishing for \(|x| > t + 1\) ; the celerity of the walk being of one space-step per time-step, and the initial condition being localized, then \(\psi_x^+(t + 1) = 0\).

\[x = -(t + 1) : \text{then } x + 1 = -t \text{ and }\]

\[
\psi_x^-(t + 1) = A_{-x} \psi_{x+1}^-(t) = A_{t+1} \prod_{i=1}^{t+1} A_i = \prod_{i=1}^{t+1} A_i.
\]

In order to compute \(\psi_x^+(t + 1)\), we discern four cases:

- \(|x| > t + 1\) : the celerity of the walk being of one space-step per time-step, and the initial condition being localized, then \(\psi_x^+(t + 1) = 0\).
- \(x = -(t+1)\) : using the same argument, \(\psi_{x-1}^+(t) = 0\) and \(\psi_x^-(t + 1) = 0\).
- \(x-(t+1)\) is odd: then \((x-1) - t\) is odd and \(x-1 \neq -t\).
- \(x-(t+1)\) is odd: then \((x-1) - t\) is odd and \(x-1 \neq -t\).
- \(x = -(t+1)\) : using the same argument, \(\psi_{x-1}^+(t) = 0\) and \(\psi_x^-\) is even.
- \(x = -(t+1)\) : using the same argument, \(\psi_{x-1}^+(t) = 0\) and \(\psi_x^-\) is even.
- \(x = -(t+1)\) : using the same argument, \(\psi_{x-1}^+(t) = 0\) and \(\psi_x^-\) is even.
- \(x = -(t+1)\) : using the same argument, \(\psi_{x-1}^+(t) = 0\) and \(\psi_x^-\) is even.

Using Theorem 1, it is straightforward to compute the probability density of the walker, which reads:

\[
P_x(t) = \begin{cases} 
\prod_{i=1}^{t} A_i^2 & \text{if } x = -t \\
0 & \text{if } x - t \text{ is odd} \\
\prod_{i=1}^{t} A_i^2 & \text{else}
\end{cases}
\]

where, the above probability density is vanishing for \(|x| > t\). Once we know the analytical expression of the probability density, we can compute the mean trajectory and variance. The first one reads:

\[
\mathbb{E}(t) = -t \prod_{i=1}^{t} A_i^2 + \sum_{k=0}^{t-1} (t - 2k)B_{k+1} \prod_{j=1}^{k} A_j^2,
\]

and the variance:

\[
\text{Var}(t) = t^2 \prod_{i=1}^{t} A_i^2 - \left( \prod_{i=1}^{t} A_i^2 - \sum_{i=0}^{t-1} (2i - t)B_{i+1} \prod_{j=1}^{i} A_j^2 \right)^2 + 
\sum_{i=0}^{t-1} (2i - t)^2B_{i+1} \prod_{j=1}^{i} A_j^2.
\]

Notice that the probability density and both the first two momenta, depend solely on the parameters \(\{A_x, B_x\}\) which we fix at the initial state. Let us now explore few examples to show how we can recover any arbitrary mean trajectory and variance by controlling the sole initial condition of the system. Suppose we need to recover a linear mean trajectory. The way to do that is setting \(A_k = 1\) and \(B_k = 0\) \(\forall k > 1\), supposed that \(A_1\) and \(B_1\) are known. Without lack of generality we set \(A_1 = (1 - B_1^2)\). Then the probability density is:

\[
P_x(t) = \begin{cases} 
(1 - B_1^2)^2 & \text{if } x = -t \\
B_1^2 & \text{if } x = t \\
0 & \text{else}
\end{cases}
\]

In this particular case, the general expression of the mean value of the trajectory reduces to:

\[
\mathbb{E}(t) = -t(1 - 2B_1^2)
\]

The pre-factor \(2B_1^2 - 1 \equiv v\), may be seen as the mean velocity of the walker. As we can see in Fig. 1 the smaller is \(v\), the smaller will be the velocity of the mean trajectory. The variance \(\text{Var}(t)\) will be of course \(\propto t^2\), which coincide with the standard ballistic behaviour of an homogeneous QW.

A second less trivial example may be represented by the parabolic mean trajectory, which translates in a non-linear variance. For example, let’s set \(B_k = \sqrt{\frac{z}{z(k-1) - 2}}\), \(z \in \mathbb{R}^+\).
Now the probability reads:

\[ P_x(t) = \begin{cases} 
1 - \frac{tz}{z+2} & \text{if } x = -t \\
0 & \text{if } x - t \text{ is odd} \\
\frac{z}{z+2} & \text{else}
\end{cases} \]

and we can consequently deduce the mean trajectory

\[ \mathbb{E}(t) = \frac{t(zt - 2)}{z+2} \]

and the standard deviation \( \sigma = \sqrt{\text{Var}(t)} \):

\[ \sigma(t) = \sqrt{\frac{t(-3t(zt - 2) + (z + 2)(-2t^2z + 3zt + 6t + 2z))}{3(z+2)^2}}. \]

Notice that the above standard deviation is not linear in time, as shown in Fig. 2 and the non-linear behaviour of \( \sigma \) strongly depends on \( z \).

In all previous particular cases, we have shown how to recover linear and non-linear moments, keeping the probability density \( P_x(t) \) either constant either linear in \( t \). In our last result, we show how it is possible to generalize these results, making the walker’s probability density follow arbitrary trajectories. This result is surprising as, although similar results have been obtained before, they required to define a local metrics for each point of the space-time lattice. More specifically, we want to show how, by paying the price of introducing quantum memory, this result can be achieved simply by acting on the initial state and therefore can be exactly controlled once for all. This translates in the following theorem:

**Theorem 2.** Let us choose

\[ B_k^2 = \frac{f_{k-1}}{1 - \sum_{i=1}^{k-2} f_i} \]

then the probability density reads:

\[ P_x(t) = \begin{cases} 
1 - \sum_{i=0}^{t-1} f_i & \text{if } x = -t \\
0 & \text{if } x - t \text{ is odd or } |x| > t \\
f_{\frac{x-t}{2}} & \text{else}
\end{cases} \]

for some arbitrary function \( f_i \) which verifies

- \( \forall t, \sum_{i=0}^{t-1} f_i \leq 1 \)
- \( \forall t, 0 \leq f_t \leq 1 \).

**Proof.** We take

\[ \begin{aligned}
B_k^2 &= \frac{f_{k-1}}{1 - \sum_{i=0}^{k-2} f_i} \\
A_k^2 &= 1 - \frac{f_{k-1}}{1 - \sum_{i=0}^{k-2} f_i}.
\end{aligned} \]

Now, we want to prove that

\[ \prod_{i=1}^{t} A_i^2 = 1 - \sum_{i=0}^{t-1} f_i \]

\[ B_{t+1}^2 \prod_{i=1}^{t} A_i^2 = f_{\frac{t}{2}}. \]

First let us prove by induction that

\[ \prod_{i=1}^{t} A_i^2 = 1 - \sum_{i=0}^{t-1} f_i. \]

• For \( t = 0 \):

\[ \prod_{i=1}^{0} A_i^2 = 1 - \sum_{i=0}^{-1} f_i = 1. \]
If it’s true for $t$, then
\[
\prod_{i=1}^{t+1} A_i^2 = A_{t+1}^2 \prod_{i=1}^{t} A_i^2 = \left(1 - \frac{f_t}{1 - \sum_{i=0}^{t-1} f_i} \right)^{t} A_i^2 \\
= \left(1 - \frac{f_t}{1 - \sum_{i=0}^{t-1} f_i} \right) \left(1 - \frac{t-1}{i=0} f_i \right) = 1 - \sum_{i=0}^{t} f_i - f_t = 1 - \sum_{i=0}^{t} f_i.
\]

So it is true for $t + 1$.

Now let us prove that
\[
B_{t,x}^2 \prod_{j=1}^{t-x} A_j^2 f = \frac{x}{t}.
\]

\[
B_{t,x}^2 \prod_{j=1}^{t-x} A_j^2 = B_{t,x+1}^2 \left(1 - \sum_{i=0}^{t-x-1} f_i \right)
\]

\[
= \left(\frac{x}{t} \right) \left(1 - \sum_{i=0}^{t-x-1} f_i \right) = \frac{x}{t}.
\]

\section*{DISCUSSION}

In conclusion, we introduced a quantum walker which interacts with a memory at each site, allowing the walker’s dynamics to depend on the state of the memory qubits in the particle’s neighborhood. We considered a scheme that parametrizes the initial states of the memory qubits, and we analytically obtain the probability density of the walker’s position, and consequently, its mean trajectory and variance. Varying these parameters alone suffices to generate a range of trajectories that may simulate motion on curved manifolds. This paves the way to implement dynamically interesting physics models, especially quantum particle propagation on curved spacetime. Indeed, embedding the mean trajectory, once for all, in the initial state of the overall QCA, is a clear computational advantage, which may reduce the resources needed for the simulation of a wide variety of dynamical physical models. Possible extensions of these results may also concern quantum algorithms. For example, such a model could inspire efficient spatial search algorithms, as an extension of single quantum walk based schemes.

\section*{ACKNOWLEDGEMENTS}

\section*{Appendix}

Recurrence relations

Let’s recall the initial state $|\Psi(0)\rangle$:

\[
|\Psi(0)\rangle = |0\rangle |v^-\rangle \left(\bigotimes_{x=-\infty}^{-1} A_{-x} |0\rangle + B_{-x} |1\rangle \right) \left(\bigotimes_{x=0}^{\infty} \right)
\]

and let’s rephrase it in the following array:

| position | $\cdots$ | $-2$ | $-1$ | $0$ | $1$ | $2$ | $\cdots$ |
| velocity | $\cdots$ | $0$ | $0$ | $1$ | $0$ | $0$ | $0$ | $\cdots$ |
| memory | $\cdots$ | $A_2$ | $A_1$ | $1$ | $1$ | $0$ | $0$ | $\cdots$ |

First action of $Q$:

$Q$ can only act on $x = 0$, on which there is $|v^-\rangle$ associated to its left and right neighbors which are in memory space $A_1 |0\rangle + B_1 |1\rangle$ (left neighbor in position $x = -1$) and $1 \times |0\rangle$ (right neighbor in position $x = +1$). So that $Q$ will act on $A_1 |v^-00\rangle + B_1 |v^-10\rangle$ and $A_1 |v^-00\rangle + B_1 |v^-10\rangle = A_1 |v^-00\rangle + B_1 |v^-01\rangle$

First shift:

The shift acts in the position velocity space on $A_1 |v^-0\rangle + B_1 |v^-1\rangle$, and its action is

$S \left(A_1 |v^-0\rangle + B_1 |v^-1\rangle \right) = A_1 |v^-1\rangle + B_1 |v^-0\rangle$

State after first iteration:

| position | $\cdots$ | $-2$ | $-1$ | $0$ | $1$ | $2$ | $\cdots$ |
| velocity | $\cdots$ | $0$ | $A_1$ | $0$ | $0$ | $0$ | $\cdots$ |
| memory | $\cdots$ | $A_2$ | $B_2$ | $1$ | $1$ | $1$ | $\cdots$ |

In position velocity space:

$\psi(1) = A_1 |v^-1\rangle + B_1 |v^-0\rangle$
So that
\[ \psi^{-1}_1 = A_1 \times 1 = A_x \psi^{-1}_{x+1}(0) \]
and
\[ \psi^+_1 = B_1 \times 1 = B_{-x+2} \psi^{-1}_{x-1}(0) \]

From there, the recurrence relations for the amplitudes \( \psi^\pm(t) \) reads:
\[ \psi^- (t + 1) = A_x \psi^+ (t) \]
\[ \psi^+ (t + 1) = B_{-x+2} \psi^- (t) \]

**Second step**:  
Now \( Q \) acts on \( x = -1 \) and \( x = 1 \) where,  
for \( A_1 |x = -1\rangle \langle v^-| \), we have for the left neighbor \( A_2 |0\rangle + B_2 |1\rangle \) and for the right neighbor \( 1 \times |0\rangle \), so that \( Q \) will act there on \( A_2 A_1 |v^- 00\rangle + B_2 A_1 |v^- 10\rangle \), resulting in  
\[ Q(A_2 A_1 |v^- 00\rangle + B_2 A_1 |v^- 10\rangle) = A_2 A_1 |v^- 00\rangle + B_2 A_1 |v^- 01\rangle \]

For \( B_1 |x = +1\rangle \langle v^+| \), we have for the left neighbor \( 1 \times |0\rangle \) and for the right neighbor \( 1 \times |0\rangle \), so that \( Q \) will act on \( B_1 |v^+ 00\rangle \), and  
\[ QB_1 |v^+ 00\rangle = B_1 |v^+ 11\rangle \]

Now the shift will act, in the position velocity space, as  
\[
S \left( A_2 A_1 |1\rangle \langle v^-| + B_2 A_1 |1\rangle \langle v^+| + B_1 |2\rangle \langle v^+| \right) = A_2 A_1 |2\rangle \langle v^-| + B_2 A_1 |0\rangle \langle v^+| + B_1 |2\rangle \langle v^+| 
\]

For the amplitudes \( \psi^\pm \), this gives:
\[
\psi^- (2) = A_2 \times A_1 = A_x \psi^+_1 (1)
\]
\[
\psi^+ (2) = B_2 \times A_1 = B_{-x+2} \psi^- (1)
\]
\[
\psi^+_2 (2) = B_1 = \psi^- (1)
\]

So that now the full recurrence relations are
\[ \psi^- (t + 1) = A_x \psi^+ (t) \]
\[ \psi^+ (t + 1) = \psi^- (t) + B_{-x+2} \psi^- (t) \]
