ABSTRACT

Background Early neurological deterioration occurs frequently after subarachnoid haemorrhage (SAH). The impact on hospital course and outcome remains poorly defined.

Methods We identified risk factors for worsening on the Hunt–Hess grading scale within the first 24 h after admission in 609 consecutively admitted aneurysmal SAH patients. Admission risk factors and the impact of early worsening on outcome was evaluated using multivariable analysis adjusting for age, gender, admission clinical grade, admission year and procedure type. Outcome was evaluated at 12 months using the modified Rankin Scale (mRS).

Results 211 patients worsened within the first 24 h of admission (35%). In a multivariate adjusted model, early worsening was associated with older age (OR 1.02, 95% CI 1.01 to 1.03; p=0.04), the presence of intracerebral haematoma on initial CT scan (OR 2.0, 95% CI 1.2 to 3.5; p=0.01) and higher SAH and intraventricular haemorrhage sum scores (OR 1.05, 95% CI 1.03 to 1.08 and 1.1, 95% CI 1.01 to 1.2; p<0.001 and 0.03, respectively). Early worsening was associated with more hospital complications and prolonged length of hospital stay and was an independent predictor of death (OR 12.1, 95% CI 5.7 to 28.1; p<0.001) and death or moderate to severe disability (mRS 4–6; OR 8.4, 95% CI 4.9 to 14.5; p=0.01) at 1 year.

Conclusions Early worsening after SAH occurs in 35% of patients, is predicted by clot burden and is associated with mortality and poor functional outcome at 1 year.

BACKGROUND

Subarachnoid haemorrhage (SAH) is associated with a high mortality and morbidity.1 The detrimental effect of medical complications in the first 2 weeks after haemorrhage on long-term outcome has been extensively studied.2–5 Additional determinants of poor outcome after SAH include age, neurological state at presentation and large aneurysm size.1 After the initial neuronal damage caused by the haemorrhage, neurological decline is often observed. Clinical worsening may occur early (within the first 24 h of admission) or late in the course of the disease. Several factors have been associated with clinical deterioration, including aneurysm rebleeding, hydrocephalus, delayed cerebral ischaemia from vasospasm, and seizures.4–6,10 However, admission variables predicting early neurological decline have not been evaluated, and the impact of early worsening on hospital course and outcome received little attention as a prognostic variable after SAH. In this study we sought to identify predictors for early worsening after SAH and to determine the impact of worsening on outcome.

METHODS

Patient population and clinical management

All SAH patients admitted to the Neurological Intensive Care Unit of Columbia University Medical Center between July 1996 and May 2009 were offered enrollment in the Columbia University SAH Outcomes Project (n=1227). Consent rate was 98%. The study was approved by the hospital institutional review board, and in all cases written informed consent was obtained from the patient or a surrogate. The diagnosis of SAH was established by admission CT scan or by xanthochromia of the CSF if CT was not diagnostic. Patients with SAH due to trauma, arteriovenous malformation, vasculitis or other structural lesions (n=242), as well as those aged <18 years (n=6) or admitted >24 h after SAH onset (n=237) and those without recorded Hunt–Hess grades on admission and worst Hunt–Hess grade within the first 24 h (n=24) were excluded. Additionally, admission Hunt–Hess grade V patients were not included in the final analysis due to inability of further deterioration (n=109). Clinical management according to guidelines set forth by the American Heart Association has been described in detail previously.3,4,11 We record the day of aneurysmal SAH as day 0 in our database.

Clinical and radiographic variables, and hospital complications

We recorded baseline demographic data, social and past medical history, clinical features at SAH onset and admission CT scan, as described previously.3,4,12,13 Neurological and general medical condition on admission was evaluated with the Hunt–Hess scale12 and the physiological subscore of the Acute Physiology and Chronic Health Evaluation (APACHE)-2 scale.13 Hunt–Hess grades on admission and at 24 h were evaluated by the treating neurointensivist (JC, NB, KL, SAM) and recorded. Hospital complications were prospectively recorded according to standardised definitions, including fever (body temperature ≥38.3°C), anaemia treated with blood transfusion (haemoglobin <9.0 g/l), aneurysm rebleeding, brainstem herniation, cerebral infarction (from any cause),
hydrocephalus treated with CSF diversion, hyperglycaemia (blood glucose >11 mmol/l), hyponatraemia (serum sodium ≤130 mmol/l), hypotension (systolic blood pressure <100 mm Hg) requiring pressors, sepsis, pneumonia, pulmonary oedema, seizures and delayed cerebral ischaemia (delayed neurological deterioration, cerebral infarction or both) due to vasospasm. The Bicaudate Index was used as an estimated measure for the development of hydrocephalus.

Early neurological deterioration
In every patient, admission Hunt–Hess grade and the worst Hunt–Hess grade within the first 24 h of admission were recorded. Early neurological deterioration was defined as any increase in Hunt–Hess scale within the first 24 h of admission, with grades 1 and II combined as a single group of good grade patients. Procedure or sedation related deterioration was not considered as ‘early neurological deterioration’. The second evaluation was done ‘sedation free’ so as to minimise the effect of sedation. If sedation was considered the culprit, then a higher score was not assigned. External ventricular drain (EVD) placement was immediately performed in symptomatic patients, even before aneurysm repair. In general, EVD was in place by the time of the second score. In patients with early neurological deterioration, hydrocephalus requiring EVD placement was performed in 27% (admission Hunt–Hess grades 1 and 2, n=24/90), 61% (admission Hunt–Hess grade 3, n=42/69) and 81% (Hunt–Hess grade 4, n=42/52). Predictors for early neurological deterioration included only variables obtained on admission (demographics, past medical history, neurological and clinical examination, laboratory analyses and radiographic findings).

Outcome variables
Survival and functional outcomes were assessed at discharge and at 3 and 12 months, using the modified Rankin Scale (mRS). Poor outcome was defined as death or moderate to severe disability (mRS 4–6) at 12 months. If a 12 month mRS was not performed, day 14 (or discharge) or 3 month evaluation was carried forward.

Statistical analysis
All statistical analyses were performed using SPSS 18 software (SPSS Inc, Chicago, Illinois, USA). Significance was judged at p<0.05. Candidate predictor variables for worsening and mortality were identified by χ² or Fisher exact tests for categorical variables and the Mann–Whitney U or two tailed t tests for continuous variables (table 1). Normality was assessed using the Kolmogorov–Smirnov test. Among similar variables that were highly intercorrelated (ie, clinical scales), only the variable with the highest OR and smallest p value in the binary logistic regression analysis was used as a candidate variable in the final multivariate model. Independent predictors of early worsening, death at 12 months and death or severe disability at 12 months were identified with backward stepwise multiple logistic regression analysis. Factors that occurred at a frequency of <5% were excluded from the final model. To determine the relative contributions of the individual predictors, we used Bayesian information criterion and Akaike’s information criterion of the entire model after individual removal of each significant predictor. Tests for interaction were performed for all variables entered into the multivariable models. When significant two way interactions were identified, we reanalysed the predictive value of each factor after stratifying the analysis between the two levels of the other factor.

RESULTS
Frequency of early neurological deterioration
Of the 609 patients eligible for analysis, early worsening occurred in 35% of patients (n=211), equally distributed in patients where aneurysm was coiled (34%) and clipped (35%). Aneurysm repair was performed on day 1 of admission (median, IQR 1–1). Early worsening occurred by one (58%, to
Hunt–Hess grade 3, n=65; to Hunt–Hess grade 4, n=42; to Hunt–Hess grade 5, n=52), two (54%; to Hunt–Hess grade 4, n=17; to Hunt–Hess grade 5, n=27) or three (8%; to Hunt–Hess grade 5, n=10) Hunt–Hess categories.

Predictors of early neurological deterioration

Of the clinical and radiographic variables associated with worsening in the univariate analysis (table 1), older age, intracerebral haematoma on initial CT scan, higher SAH sum and intraventricular haemorrhage sum scores were independent predictors of worsening within the first 24 h (table 2), after adjusting for admission Hunt–Hess grade, gender, admission year and procedure type (surgical/endovascular treatment of ruptured aneurysms). No interactions were found between these predictors in this final model.

Hospital complications

The rate of hospital complications was higher in patients with early neurological deterioration, as shown in table 3.

Table 2  Multivariate analysis predicting neurological deterioration in the first 24 h

| Variable                                      | OR    | 95% CI      | p Value |
|-----------------------------------------------|-------|-------------|---------|
| Age                                           | 1.02  | 1.001 to 1.03 | 0.04   |
| Intracerebral haematoma on initial CT          | 2.0   | 1.2 to 3.5  | 0.01   |
| SAH sum score†                                 | 1.05  | 1.03 to 1.08 | <0.001 |
| IVH sum score†                                 | 1.1   | 1.01 to 1.18 | 0.03   |

*Adjusted for gender, admission Hunt–Hess grade, admission year and surgical/endovascular treatment.
†SAH and IVH sum scores are as described in the legend to table 1. IVH, intraventricular haemorrhage; SAH, subarachnoid haemorrhage.

Table 3  Hospital complications and outcome in relation to neurological deterioration in the first 24 h (n=609)

|                        | Worse (n=211) | Stable (n=398) | p Value |
|------------------------|--------------|----------------|---------|
| Fever >38.3°C           | 153 (73)     | 184 (46)       | <0.001  |
| Anaemia treated with blood transfusion      | 114 (54)     | 115 (29)       | <0.001  |
| Aneurysm rebleeding     | 35 (17)      | 15 (4)         | <0.001  |
| Herniation              | 52 (25)      | 18 (5)         | <0.001  |
| Hydrocephalus treated with CSF diversion     | 108 (51)     | 104 (26)       | <0.001  |
| Hyperglycaemia (>11 mmol/l)                  | 124 (59)     | 171 (43)       | <0.001  |
| Hyponatraemia (<130 mmol/l)                  | 36 (17)      | 59 (15)        | 0.477   |
| Hypotension requiring vasopressors           | 67 (32)      | 65 (16)        | <0.001  |
| Pneumonia                | 82 (39)      | 58 (15)        | <0.001  |
| Pulmonary oedema         | 68 (32)      | 44 (11)        | <0.001  |
| Seizure                  | 25 (12)      | 15 (4)         | <0.001  |
| Sepsis                   | 41 (19)      | 31 (8)         | <0.001  |
| Delayed cerebral ischaemia | 73 (35)   | 61 (15)        | <0.001  |
| ICU LOS                  | 13 (9–19)    | 9 (7–12)       | <0.001  |
| Hospital LOS             | 20 (13–31)   | 13 (11–19)     | <0.001  |

Values are presented as median (IQR) or number (%). \( \chi^2 \); Fisher exact tests or Mann–Whitney U or two tailed t tests were used as appropriate.

DISCUSSION

We found that early neurological deterioration after SAH is a strong predictor of death and poor functional recovery at 1 year. Older age and overall clot burden on admission predicted clinical worsening.

The most novel finding in this study is that the initial haemorrhage load is an independent predictor for early neurological deterioration after SAH, regardless of whether the blood is intraventricular, intracerebral or in the subarachnoid space. The association of clot burden and early neurological deterioration may be explained by the evolving mass effect with intracerebral haemorrhage or through the development of obstructive hydrocephalus in patients with intraventricular bleeding. Although we did not find an association between the Bicaudate Index on admission and neurological deterioration, patients may have developed hydrocephalus thereafter.

One can only speculate why the amount of subarachnoid blood in direct contact with the brain predicts early neurological deterioration. It may be that the toxicity of blood drives early metabolic and electrical failure of brain cells. This concept of neurohaemoinflammation is based on mechanical, biochemical and molecular changes, eventually leading to oedema, neurovascular uncoupling, apoptosis and cell death. Carefully designed studies using multimodal neuromonitoring techniques (microdialysis, brain tissue oxygen and EEG monitoring) or neuroimaging modalities (MR, positron emission tomography, single photon emission computed tomography) may capture these early pathophysiological changes in brain metabolism and physiology.

Given the observed association between clot burden and early worsening, another target for intervention may be found in decreasing haemorrhage related energy demand of the acutely injured brain after poor grade SAH by pharmacological measures or hypothermia. Although intraoperative hypothermia does not improve outcome during aneurysm clipping, early and more prolonged hypothermia may be beneficial as a means of reducing cerebral energy demand or the tissue inflammatory response. Another strategy to minimise the harmful effects of subarachnoid and intraventricular blood might include cisternal or ventricular lavage, kinetic therapy or other methods for promoting early blood clearance. Early evacuation of packed intraventricular haemorrhage in poor grade SAH patients, however, did not show a favourable outcome.

There is some evidence that lumbar drainage of CSF decreases symptomatic vasospasm and improves outcome after SAH.
The most common hospital complication been associated with inhospital complications and increased mortality. The strong association between worsening and delay in SAH is a widely accepted management strategy and may improve outcome.29 Several potential weaknesses of this study deserve mention. The single centre design of our study limits the generalisability of our results. The major limitation of this study is that other factors, which potentially cause early neurological deterioration (seizures, stunned myocardium, fever, etc.) were not investigated as these data were not recorded in a time locked way in our database. Furthermore, our data provide no information on early worsening in Hunt–Hess grade V patients, as they were not included in our analysis. Patients may deteriorate prior to hospital admission and after the first 24 h, and our study provides no data on these events. Finally, we analysed only admission predictors of neurological worsening. Due to the complex nature of neurological injury in SAH, we found it impossible to reliably identify specific complications, such as intracranial hypertension, obstructive hydrocephalus, brainstem herniation, seizures, rebleeding or acute cerebral infarctions as the primary cause of early worsening in individual patients. Although we record these complications in our database, we also do not have information regarding the timing of these events. Moreover, the exact hour of SAH bleeding and the exact time of neurological deterioration after admission was not recorded prospectively, which could also have influenced our results. If a 12 month mRS was not performed, the day 14 (or discharge) or 3 month evaluation was carried forward. The model predicting 1 year outcome was recalculated without patients with missing 12 month evaluations (50%) and did not show a significant change in variables.

### Table 4

| Variable                                      | OR  | 95% CI     | p Value | OR  | 95% CI     | p Value |
|-----------------------------------------------|-----|------------|---------|-----|------------|---------|
| Age                                           | 1.05| 1.02 to 1.07| <0.001  | 1.05| 1.02 to 1.07| <0.001  |
| Admission Hunt–Hess                           | 2.6 | 1.9 to 3.4  | <0.001  | 2.3 | 1.6 to 3.3  | <0.001  |

| Neurological deterioration in first 24 h       | 8.4 | 4.9 to 14.5 | <0.001  | 12.1| 5.7 to 26.1 | <0.001  |

*Adjusted for gender, admission year and surgical/endovascular treatment.
†Defined as modified Rankin Scale >3.
‡Hyperglycaemia (≥11 mmol/l) at any point during hospitalisation.

CONCLUSIONS

In conclusion, our findings indicate that early neurological deterioration is an important predictor of poor outcome after SAH. Carefully designed prospective studies are needed to understand the pathophysiology of this phenomenon. Medical therapies aimed at preventing early deterioration after SAH may improve outcome.
