Abstract. Consider the continuum of points along the edges of a network, i.e., a connected, undirected graph with positive edge weights. We measure the distance between these points in terms of the weighted shortest path distance, called the network distance. Within this metric space, we study farthest points and farthest distances. We introduce a data structure supporting queries for the farthest distance and the farthest points on two-terminal series-parallel networks. This data structure supports farthest-point queries in $O(k + \log n)$ time after $O(n \log p)$ construction time, where $k$ is the number of farthest points, $n$ is the size of the network, and $p$ parallel operations are required to generate the network.

1 Introduction

Consider the continuum of points on the edges of a network, i.e., a connected, undirected graph with positive edge weights. We measure the distance between these points in terms of the weighted shortest path distance, called the network distance. Within this metric space, we study farthest points and farthest distances. We introduce a data structure supporting queries for the farthest distance and the farthest points on two-terminal series-parallel networks.

As a prototype application, imagine the task to find the ideal location for a new hospital within the network formed by the streets of a city. One criteria for this optimization would be the emergency unit response time, i.e., the worst-case time an emergency crew needs to drive from the hospital to the site of an accident. However, the ideal location in terms of emergency unit response time may be unacceptable with respect to another measure of how ideal a location is. We provide a data structure that would allow a decision maker to quickly compare various locations in terms of emergency unit response time.

We obtain our data structure for two-terminal series-parallel networks by studying simpler networks reflecting parallel structure (parallel-path) and serial structure (bead-chains). Combining these insights, we support queries on flat series-parallel networks (abacus). Finally, we decompose series-parallel networks into a tree of nested abaci and combine their associated data structures.

Our focus on supporting human decision makers with data structures deviates from the common one-shot optimization problems in location analysis, where we assume that only one factor determines suitable locations for some facility in a network. Moreover, we illustrate new ways of exploiting different parallel structures of networks that may be useful for tackling related problems.
1.1 Preliminaries

A network is defined as a simple, connected, undirected graph \( N = (V, E) \) with positive edge weights. We write \( w_{uv} \) to denote weight of the edge \( uv \in E \) that connects the vertices \( u, v \in V \). A point \( p \) on edge \( uv \) subdivides \( uv \) into two sub-edges \( up \) and \( pv \) with \( w_{up} = \lambda w_{uv} \) and \( w_{pv} = (1 - \lambda)w_{uv} \), for some \( \lambda \in [0, 1] \). We write \( p \in uv \) when \( p \) is on edge \( uv \) and \( p \in N \) when \( p \) is on some edge of \( N \). The network distance between \( p, q \in N \), denoted by \( d_N(p, q) \), is measured as the weighted length of a shortest path from \( p \) to \( q \) in \( N \). We denote the farthest distance from \( p \) by \( \bar{d}_N(p) \), i.e., \( \bar{d}_N(p) = \max_{q \in N} d_N(p, q) \). Accordingly, we say a point \( \bar{p} \) on \( N \) is farthest from \( p \) if and only if \( d_N(p, \bar{p}) = \bar{d}_N(p) \).

We develop data structures supporting the following queries in a network \( N \). Given a point \( p \) on \( N \), what is the farthest distance from \( p \)? What are the farthest points from \( p \) in \( N \)? We refer to the former as farthest-distance query and to the latter as farthest-point query. The query point \( p \) is represented by the edge \( uv \) containing \( p \) together with the value \( \lambda \in [0, 1] \) such that \( w_{up} = \lambda w_{uv} \).

Fig. 1. The series operation and the parallel operation (a) that are used to generate two-terminal series-parallel networks (b). The colors in (b) indicate the creation history.

The term series-parallel network stems from the following two operations that are illustrated in Fig. 1. The series operation splits an existing edge \( uv \) into two new edges \( ux \) and \( xv \) where \( x \) is a new vertex. The parallel operation creates a copy of an existing edge. A network \( N \) is two-terminal series-parallel when its underlying graph can be generated from a single edge \( uv \) using a sequence of series and parallel operations; the vertices \( u \) and \( v \) are called terminals of \( N \). We refer to the number of parallel operations required to generate \( N \) as the parallelism of \( N \) and to the number of series operations as the serialism of \( N \).

A network is called series-parallel when every bi-connected component is two-terminal series-parallel with respect to any two vertices. In this work, we only consider bi-connected networks; in the full version, we shall adapt our treatment of multiple bi-connected components from cacti to series-parallel networks.

\(^{3}\) The final graph is simple even if intermediate graphs have loops and multiple edges.
1.2 Related Work

Duffin [6] studies series-parallel networks to compute the resistance of circuit boards. He characterizes three equivalent definitions of series-parallel networks and establishes their planarity. Valdes et. al. [14] recognize and decompose directed series-parallel networks in linear time. Several problems that are NP-hard on general networks have linear time algorithms on two-terminal series-parallel networks, e.g., including the minimum vertex cover and maximum cycle problem [2,13].

A network Voronoi diagram subdivides a network depending on which site among a finite set of points of interest is closest [9] or farthest [7,12]. Any data structure for farthest-point queries on a network represents a network farthest-point Voronoi diagrams where all points on the network are considered sites [3].

A continuous absolute center is a point on a network with minimum farthest-distance. Computing a continuous absolute center takes $O(n)$ time on cacti [1] and $O(m^2 \log n)$ time on general networks [10]. As a by-product, we obtain all continuous absolute centers of a series-parallel network in $O(n \log p)$ time.

1.3 Structure and Results

We introduce a data structure supporting queries for the farthest distance and the farthest points on two-terminal series-parallel networks. We obtain this data structure by isolating different sub-structures of series-parallel networks: In Sections 2 and 3, we study networks consisting of parallel paths and networks consisting of a cycle with attached paths (bead-chains), respectively. In Section 4, we combine these results into abacus networks, which are series-parallel networks without nested structures. Finally, we combine these intermediate data structures to obtain our main result in Section 5. Table 1 summarizes the characteristics of the proposed data structures and compares them to previous results.

| Type            | Farthest-Point Query | Size       | Construction | Time        | Reference |
|-----------------|----------------------|------------|--------------|-------------|-----------|
| General         | $O(k + \log n)$      | $O(m^2)$   | $O(m^2 \log n)$ |            | [3]       |
| Tree            | $O(k)$               | $O(n)$     | $O(n)$       |             | [4]       |
| Cycle           | $O(\log n)$         | $O(n)$     | $O(n)$       |             | [4]       |
| Uni-Cyclic      | $O(k + \log n)$     | $O(n)$     | $O(n)$       |             | [4]       |
| Cactus          | $O(k + \log n)$     | $O(n)$     | $O(n)$       |             | [4]       |
| Parallel-Path   | $O(k + \log n)$     | $O(n)$     | $O(n)$       |             | this work |
| Bead-Chain      | $O(k + \log n)$     | $O(n)$     | $O(n)$       |             | this work |
| Abacus          | $O(k + \log n)$     | $O(n)$     | $O(n \log p)$|             | this work |
| Series-Parallel | $O(k + \log n)$     | $O(n)$     | $O(n \log p)$|             | this work |

Table 1. The traits of our data structures for queries in different types of networks, with $n$ vertices, $m$ edges, $k$ reported farthest points, and parallelism $p$. 

3
2 Parallel-Path Networks

A parallel-path network consists of a bundle of edge disjoint paths connecting two vertices \( u \) and \( v \), as illustrated in Fig. 2. In terms of series-parallel networks, parallel-path networks are generated from an edge \( uv \) using a sequence of parallel operations followed by a sequence of series operations.

Let \( P_1, P_2, \ldots, P_p \) be the paths of weighted lengths \( w_1 \leq w_2 \leq \cdots \leq w_p \) between the terminals \( u \) and \( v \) in a parallel-path network \( N \). Consider a shortest path tree \(^4\) from a query point \( q \in N \). As depicted in Fig. 3, there are three cases: either all shortest paths from \( q \) reach \( v \) via \( u \) (left case), or all shortest paths from \( q \) reach \( u \) via \( v \) (right case), or neither (middle case). We distinguish the three cases using the following notation. Let \( \bar{x}_i \) denote the farthest point from \( x \in \{ u, v \} \) among the points of path \( P_i \), i.e., \( \bar{x}_i \) is a point on \( P_i \) such that \( d(x, \bar{x}_i) = \max_{y \in P_i} d(x, y) \). Together with Fig. 3, the next lemma justifies our choice of the names left case, middle case, and right case.

**Lemma 1.** Consider a query \( q \) from the \( i \)-th path of a parallel-path network.

(i) We are in the left case when \( q \) lies on the sub-path from \( u \) to \( \bar{v}_i \) with \( q \neq \bar{v}_i \),
(ii) we are in the middle case when \( q \) lies on the sub-path from \( \bar{v}_i \) to \( \bar{u}_i \), and
(iii) we are in the right case when \( q \) lies on the sub-path from \( \bar{u}_i \) to \( v \) with \( q \neq \bar{u}_i \).

\(^4\) More precisely, we consider extended shortest path trees \(^1\) which result from splitting each non-tree edge \( st \) of a shortest path tree into two sub-edge \( sx \) and \( xt \), where all points on \( sx \) reach the root through \( s \) and all points on \( xt \) reach the root through \( t \).
Proof. Assume we are in the left case, where every shortest path from the query point \( q \in P_i \) to \( v \) contains \( u \), i.e., \( d(q, v) = d(q, u) + d(u, v) \) and \( d(q, v) < w_{qu} \). The latter implies \( q \neq \tilde{v}_i \), since \( d(v, \tilde{v}_i) = w_{vq} \). Moreover, \( \tilde{v}_i \) cannot lie on the sub-path from \( q \) to \( u \) along \( P_i \), since otherwise

\[
d(q, v) = d(q, \tilde{v}_i) + d(\tilde{v}_i, v) > d(\tilde{v}_i, v),
\]

contradicting the choice of \( \tilde{v}_i \) as farthest point from \( v \) on \( P_i \). Therefore, \( q \) must lie between \( u \) and \( \tilde{v}_i \) along \( P_i \) when we are in the left case.

Conversely, assume \( q \) lies between \( u \) and \( \tilde{v}_i \) along \( P_i \) with \( q \neq \tilde{v}_i \). No shortest path from \( q \) to \( v \) can contain \( \tilde{v}_i \) in its interior. Hence, every shortest path from \( q \) to \( v \) reaches \( v \) via \( u \), i.e., the left case applies. Symmetrically, the right case applies if and only if \( q \neq u_i \) lies between \( u_i \) and \( v \). Consequently, only the middle case remains for all points on the sub-path from \( \tilde{v}_i \) to \( u_i \) and the claim follows. \( \square \)

Using Lemma 1 we deal with the three cases as follows.

**Left Case and Right Case** In the left case, every shortest path from \( q \in P_i \) to any point outside of \( P_i \) leaves \( P_i \) through \( u \). Hence, the farthest point from \( q \) on \( P_j \) with \( j \neq i \) is the farthest point \( \tilde{u}_j \) from \( u \) on \( P_j \). The distance from \( q \) to \( \tilde{u}_j \) is \( d(q, \tilde{u}_j) = d(q, u) + d(u, \tilde{u}_j) = w_{qu} + \frac{w_{1} + w_{j}}{2} \). On the other hand, the farthest point \( \tilde{v}_i \) from \( q \) on \( P_i \) itself moves from \( \tilde{u}_i \) to \( v \) as \( q \) moves from \( u \) to \( \tilde{v}_i \) maintaining a distance of \( d(q, \tilde{v}_i) = \frac{w_{qu} + w_{v}}{2} \). Therefore, the farthest distance from \( q \) in \( N \) is

\[
\tilde{d}(q) = \max \left[ \frac{w_{1} + w_{i}}{2}, \max_{j \neq i} \left( w_{qu} + \frac{w_{1} + w_{j}}{2} \right) \right] =
\begin{cases} 
    \frac{w_{qu} + w_{v}}{2} & \text{if } i \neq p \\
    \frac{w_{qu} + w_{1} + w_{p-1}}{2} & \text{if } i = p \text{ and } \frac{w_{p} - w_{p-1}}{2} \leq w_{qu} \\
    \frac{w_{1} + w_{p}}{2} & \text{if } i = p \text{ and } \frac{w_{p} - w_{p-1}}{2} \geq w_{qu}
\end{cases}
\]

The first case means that the farthest points lie on the longest \( u-v \)-paths for queries outside of the longest \( u-v \)-path \( P_p \). The second and third case distinguish whether \( P_p \) contains a farthest point for queries from \( P_p \) itself. Accordingly, we answer a farthest point query from \( q \in P_i \) in the left case as follows.

- If \( i \neq p \), we report all \( \tilde{u}_j \) where \( w_{j} = w_{p} \) and \( i \neq j \).
- If \( i = p \) and \( \frac{w_{p} - w_{p-1}}{2} \leq w_{qu} \), we report all \( \tilde{u}_j \) where \( w_{j} = w_{p-1} \) and \( j \neq p \).
- If \( i = p \) and \( \frac{w_{p} - w_{p-1}}{2} \geq w_{qu} \), we report the farthest point \( \tilde{q}_p \) from \( q \) on \( P_p \) using a binary search along the sub-path of \( P_p \) from \( \tilde{u}_p \) to \( v \).

The overlap between the last two cases is intentional and covers a boundary case. With this approach, answering a farthest-point query takes \( O(k + \log n) \) time.
Middle Case. In the middle case, there are no farthest points from \( q \) on \( P_i \) itself and every path \( P_j \) with \( j \neq i \) contains points that we reach from \( q \) via \( u \) as well as points that we reach from \( q \) via \( v \). Let \( \bar{q}_j \) be the farthest point from \( q \) along the cycle formed by \( P_j \) and \( P_i \). Since the distance from \( q \) to \( \bar{q}_j \) is \( d(q, \bar{q}_j) = \frac{w_i + w_j}{2} \), the farthest distance \( \bar{d}(q) \) from \( q \) in \( N \) is

\[
\bar{d}(q) = \max_{j \neq i} \left( \frac{w_i + w_j}{2} \right) = \begin{cases} \frac{w_i + w_j}{2} & \text{if } i \neq p \\ \frac{w_p + w_{p-1}}{2} & \text{if } i = p \end{cases}
\]

The first case applies for queries from anywhere other than \( P_p \) who have their farthest points on the longest \( u \)-\( v \)-paths, i.e., on the paths \( P_j \) with \( w_j = w_p \). The second case applies for queries from \( P_p \) who have their farthest points on the second longest \( u \)-\( v \)-paths, i.e., on the paths \( P_j \) with \( w_j = w_{p-1} \). We could answer a farthest point query from \( q \) \( \in P_i \) in the middle case by reporting the points \( \bar{q}_j \) for the right indices \( j \) using binary search on the \( k \) paths containing farthest points. To improve the resulting query time of \( O(k \log n) \), we take a closer look at the position of \( \bar{q}_j \) relative to \( \bar{u}_j \) and \( \bar{v}_j \). As illustrated in Fig. 4, the farthest point \( \bar{q}_j \) from \( q \) \( \in P_i \) along \( P_j \) moves from \( \bar{u}_j \) to \( \bar{v}_j \) as \( q \) moves from \( \bar{v}_j \) to \( \bar{u}_j \).

**Lemma 2.** Let \( N \) be a parallel-path network with terminals \( u \) and \( v \). For any point \( x \in N \), let \( \bar{x}_i \) denote the farthest point from \( x \) along the \( u \)-\( v \)-path \( P_i \).

(i) The sub-path from \( \bar{v}_i \) to \( \bar{u}_i \) has length \( d(u, v) \).

(ii) For every point \( q \) along the sub-path from \( \bar{v}_i \) to \( \bar{u}_i \), the sub-path from \( \bar{v}_i \) to \( q \) has the same length as the sub-path from \( \bar{u}_j \) to \( \bar{q}_j \), i.e., \( w_{\bar{v}_i q} = w_{\bar{u}_j \bar{q}_j} \).

**Proof.** We have \( w_{\bar{u}_i \bar{v}_i} = w_{\bar{v}_i \bar{u}_i} \) for every path \( P_i \), since

\[ w_{\bar{u}_i \bar{v}_i} + w_{\bar{v}_i \bar{u}_i} = w_{\bar{u}_i \bar{v}_i} = \frac{d(u, v) + w_i}{2} = w_{\bar{v}_i \bar{u}_i} = w_{\bar{u}_i \bar{v}_i} \]

The above implies the first claim, since adding a nutritious zero yields

\[ w_{\bar{u}_i \bar{v}_i} = w_{\bar{v}_i \bar{u}_i} + (w_{\bar{u}_i \bar{v}_i} - w_{\bar{v}_i \bar{u}_i}) = d(u, v) - w_{\bar{u}_i \bar{v}_i} = d(u, v) + w_{\bar{v}_i \bar{u}_i} - w_{\bar{v}_i \bar{u}_i} = d(u, v) \]

For the second claim, we compare the length of the shortest path from \( q \) to \( \bar{q}_j \) via \( v \) with the one via \( u \). By studying Fig. 4 we obtain the following.

\[ d(q, \bar{q}_j) = w_{q\bar{v}_i} + w_{\bar{v}_i u} + w_{u\bar{v}_j} + w_{\bar{v}_j \bar{a}_j} - w_{\bar{q}_j \bar{a}_j} \]  
\[ d(q, \bar{q}_j) = w_{q\bar{u}_j} + w_{\bar{u}_j v} + w_{v\bar{a}_j} + w_{\bar{v}_j \bar{u}_i} - w_{\bar{q}_j \bar{a}_j} \]  

We generate nutritious zeros from the identities \[ w_{q\bar{v}_i} = w_{\bar{v}_u \bar{v}_i}, w_{u\bar{v}_j} = w_{\bar{v}_j \bar{u}_i}, \text{ and } w_{\bar{u}_i \bar{v}_i} = d(u, v) = w_{\bar{u}_i \bar{v}_i} \]. Rearranging terms yields the second claim, as

\[ 2w_{q\bar{v}_i} = 2w_{q\bar{v}_i} + w_{\bar{v}_u \bar{v}_i} - w_{\bar{v}_u \bar{v}_i} + w_{u\bar{v}_j} - w_{u\bar{v}_j} + w_{\bar{v}_j \bar{a}_j} - w_{\bar{v}_j \bar{a}_j} + 2(w_{q\bar{u}_j \bar{a}_j} - w_{q\bar{u}_j \bar{a}_j}) \]

\[ d(q, \bar{q}_j) - d(q, \bar{q}_j) + 2w_{q\bar{v}_i} = 2w_{q\bar{v}_i} \]  

\[ d(q, \bar{q}_j) - d(q, \bar{q}_j) + 2w_{q\bar{v}_i} = 2w_{q\bar{v}_i} \]  

\[ \square \]
Using Lemma 2, we interpret the searches for $\bar{q}_j$ on the sub-path from $\bar{v}_j$ to $\bar{u}_j$, as a single search with a common key $\bar{q}$ in multiple lists (the $\bar{v}_i$-$\bar{u}_i$-sub-paths) of comparable search keys (the vertices along these sub-paths). Using $O(n)$ time, we construct a fractional cascading data structure supporting predecessor queries on the sub-paths from $\bar{v}_j$ to $\bar{u}_j$ for those paths $P_j$ where $w_j = w_{p-1}$.

We answer a farthest-point query from $q \in P_i$ as follows. If $i \neq p$, we locate and report $\bar{q}_p$ along $P_p$ in $O(\log n)$ time. If $i = p$ or $w_p = w_{p-1}$, the remaining farthest points from $q$ are the $\bar{q}_j$ where $j \neq i$ and $w_j = w_{p-1}$; we report them in $O(k + \log n)$ time using the fractional cascading data structure. This query might report a point on $P_i$, which would be $\bar{q}_i$ for queries from outside $P_i$. For queries from within $P_i$, we omit this artifact.

**Theorem 1.** Let $N$ be a parallel-path network with $n$ vertices. There is a data structure with $O(n)$ size and $O(n)$ construction time supporting $O(k + \log n)$-time farthest-point queries on $N$, where $k$ is the number of farthest points.

### 3 Bead-Chain Networks

A bead-chain network consists of a main cycle with attached arcs so that each arc returns to the cycle before the next one begins. An example is depicted in Fig. 5. Bead-chains are series-parallel networks where we first subdivide a cycle using series operations, then we apply at most one parallel operation to each edge of this cycle followed by series operations that further subdivide the arcs and cycle.

Consider a bead-chain network $N$ with main cycle $C$ and arcs $\alpha_1, \ldots, \alpha_s$. Let $a_i$ and $b_i$ be the vertices connecting $C$ with the $i$-th arc. Without loss of generality, the path $\beta_i$ from $a_i$ to $b_i$ along $C$ is at most as long as $\alpha_i$. Otherwise, we swap the roles of $\alpha_i$ and $\beta_i$.

We first study the shape of the function $\hat{d}_i(x)$ that describes the farthest distance from points along the main cycle to any point on the $i$-th arc, i.e., $\hat{d}_i(x) = \max_{y \in \alpha_i} d(x, y)$. When considering only the $i$-th arc, we have a parallel-path network with three paths. Let $\hat{x}$ denote the farthest point from $x \in C$ on the main cycle and let $\hat{x}_i$ denote the farthest point from $x$ on arc $\alpha_i$. From the analysis in the previous section, we know that $\hat{d}_i(x)$ has the shape depicted in Fig. 6. When walking along the main cycle, we encounter $a_i$, $b_i$, $\bar{a}_i$, and $\bar{b}_i$.
in this order or its reverse. From $a_i$ to $b_i$, the point $\hat{x}_i$ moves from $\hat{a}_i$ to $\hat{b}_i$ maintaining a constant distance. From $b_i$ to $\tilde{a}_i$, the point $\hat{x}_i$ stays at $\hat{b}_i$ increasing in distance. From $b_i$ to $\hat{a}_i$, the point $\hat{x}_i$ moves from $\hat{b}_i$ back to $\hat{a}_i$, again, at a constant distance. Finally, $\hat{x}_i$ stays at $\hat{a}_i$ with decreasing distance when $x$ moves from $\tilde{b}_i$ to $a_i$. Finally, we observe that the increasing and decreasing segments of any two functions $\hat{d}_i$ and $\hat{d}_j$ have the same (unit) slope up to the sign.

Fig. 6. The shape of the function $\hat{d}_i(x)$ describing the distance from $x \in C$ to the farthest point $\hat{x}_i$ from $x$ among the points on the $i$-th arc $\alpha_i$.

The upper envelope $\hat{D}$ of the functions $\hat{d}_1, \ldots, \hat{d}_s$ indicates the farthest distance from $q \in C$ to any point on an arc and the $i$-th arc is farthest from $q$ when $\hat{d}_i$ coincides with $\hat{D}$ at $q$. We construct $\hat{D}$ in linear time using the shape the functions $\hat{d}_1, \ldots, \hat{d}_s$. We consider an arc $\alpha_i$ to be overlong when the path $\beta_i$ is longer then remainder $\gamma_i$ of the cycle, as illustrated in Fig. 7.

Fig. 7. An overlong arc $\alpha_i$ (blue) in a bead-chain network where $\beta_i$ (green) is longer then the remaining cycle $\gamma_i$ (orange). The shape of $\hat{d}_i$ is the same as for non-overlong arcs, but its high plateau may horizontally overlap with the high plateau of other arcs.
Computing the upper envelope

Assume, for a contradiction that there are two increasing segments

We proceed in two passes: in the first pass, we consider only the high plateau of \( \hat{d} \) between \( \bar{a} \) and \( \bar{b} \). This insertion by walking from \( \bar{a} \) to \( \bar{b} \) like to obtain \( \hat{d} \). In the first pass, we construct \( \hat{d} \) extending its non-constant segments and let \( \hat{d}' \) appear along the cycle and no two high plateaus overlap horizontally.

Let \( \alpha_1, \ldots, \alpha_s \) be the non-overlong arcs of \( N \) as they appear along the cycle. For every arc \( \alpha_i \), with \( i = 1, \ldots, s \), the farthest points \( a_i \) and \( b_i \) of the endpoints \( a_i \) and \( b_i \) of \( \alpha_i \) appear along \( \gamma_i \). Therefore, the points \( a_1, b_1, a_2, b_2, \ldots, a_s, b_s \) appear in this order along the cycle \( C \). Claim (i) follows, since the high plateau of \( \hat{d} \) lies between \( \bar{a} \) and \( \bar{b} \). Claim (ii) follows, since the any non-overlong arc \( \alpha_i \) has its low plateau along \( \beta_i \) and since \( \beta_1, \ldots, \beta_s \) are separate by definition. \( \square \)

As suggested by Lemma 3, we incrementally construct the upper envelope of the functions \( \hat{d}_i \) corresponding to non-overlong arcs and treat a potential overlong arc separately. When performing a farthest-point query from the cycle, we first determine the farthest distance to the overlong arc and the farthest distance to all other arcs. Depending on the answer we report farthest points accordingly.

Lemma 4. Let \( \alpha_1, \ldots, \alpha_s \) be the arcs of a bead-chain that has no overlong arc. Computing the upper envelope \( \bar{D} \) of \( \hat{d}_1, \ldots, \hat{d}_s \) takes \( O(s) \) time.

Proof. We proceed in two passes: in the first pass, we consider only the high plateaus and non-constant segments of \( \hat{d}_1, \ldots, \hat{d}_s \); the respective low plateaus are replaced by extending the corresponding non-constant segments. In the second pass, we traverse the partial upper envelope once more and compare it with the previously omitted low plateaus, thereby constructing \( \bar{D} \).

Let \( \hat{d}_i \) be the function resulting from replacing the low plateau of \( \hat{d}_i \) by extending its non-constant segments and let \( \hat{D}_i \) be the upper envelope of \( \hat{d}_1, \ldots, \hat{d}_i \). In the first pass, we construct \( \hat{D}_i \) incrementally. Assume we have \( \hat{D}_{i-1} \) and would like to obtain \( \hat{D}_i \) by inserting \( \hat{d}_i \) into \( \hat{D}_{i-1} \), as depicted in Fig. 8. We perform this insertion by walking from \( \bar{a}_i \) — the left endpoint of the high plateau of \( \hat{d}_i \) — in both directions updating the current upper envelope \( \hat{D}_{i-1} \). Locating \( \bar{a}_i \) takes constant time, since \( \bar{a}_i \) is the first bending point to the right of \( \bar{b}_{i-1} \).

There is no more than one increasing segment of \( \hat{D}_{i-1} \) between \( \bar{a}_i \) and \( \bar{b}_i \). Assume, for a contradiction that there are two increasing segments \( s_1 \) and \( s_2 \) between \( \bar{a}_i \) and \( \bar{b}_i \). Neither of them has its higher endpoint between \( \bar{a}_i \) and \( \bar{b}_i \), since there would be two horizontally overlapping high plateaus, otherwise. Since \( s_1 \) and \( s_2 \) have the same slope, only one of them can be part of the upper envelope.\(^5\) Analogously, the same holds for decreasing segments. Therefore, inserting the high plateau of \( \hat{d}_i \) into the upper envelope \( \hat{D}_{i-1} \) takes constant time.

---

\(^5\) When the segments \( s_1 \) and \( s_2 \) happen to overlap, we consider only the segment of the arc distance function that was inserted first to be part of the upper envelope.
Fig. 8. An incremental step where we construct $\hat{D}'$ from $\hat{D}_{i-1}'$ (black) and $\hat{d}'_i$ (orange). The treatment of the low plateau of $\hat{d}_i$ (dashed) is deferred to the second pass.

If the decreasing segment of $\hat{d}'_i$ appears along $\hat{D}'_i$ at all, then it appears at $\bar{b}_i$. We update the previous upper envelope $\hat{D}'_{i-1}$ by walking from $b_i$ towards $a_i$ until the decreasing segment of $\hat{d}'_i$ vanishes below $\hat{D}'_{i-1}$. We charge the costs for this walk to the segments that are removed from the previous upper envelope $\hat{D}'_{i-1}$ in the process. We proceed in the same fashion with the increasing segment of $\hat{d}'_i$ by walking from $\bar{a}_i$ towards $b_i$. Each non-constant segment appears at most once along any intermediate upper envelope and is never considered again after its removal. Therefore, the total cost for all insertions of non-constant segments—and, thus, the total cost of constructing $\hat{D}'_s$—amounts to $O(s)$.

In the second pass, we construct the desired upper envelope $\hat{D}$ by building the upper envelope of $\hat{D}_s'$ and the low plateaus of $\hat{d}_1', \ldots, \hat{d}_s'$. Since no two low plateaus overlap horizontally, we simply walk along $\hat{D}'_s$ comparing its height to the height of the current low plateau, if any. This takes $O(s)$ time, since $\hat{D}'_s$ has $O(s)$ bending points and since there are $s$ low plateaus.

We seek to answer queries identifying the farthest arcs, i.e., arcs containing farthest points, from a query point $q \in C$. If each point along the main cycle has exactly one farthest arc, we simply need to identify the segment defining the upper envelope on the sub-edge containing the query point $q$. However, there could be multiple farthest arcs when several functions among $\hat{d}_1', \ldots, \hat{d}_s'$ overlap along the upper envelope. We can store the at most two farthest arcs from plateaus directly with the corresponding segments of $\hat{D}$. However, storing the farthest arcs from increasing and decreasing segments directly could result in quadratic space and construction time. Instead, we rely on the following observation. An arc $\alpha$ is considered relevant when there exists some point $x \in C$ such that $\alpha$ is a farthest arc for $x$ and $\alpha$ is considered irrelevant when there is no such point.
Lemma 5. Let $\alpha_i$, $\alpha_j$, and $\alpha_k$ be arcs that appear in this order in a bead-chain without overlong arc. The arc $\alpha_j$ is irrelevant when $\alpha_i$ and $\alpha_k$ are farthest arcs from some query point $q$ such that $\hat{d}_i$ and $\hat{d}_k$ are both decreasing/increasing at $q$.

Proof. As illustrated in Fig. 9, $q$ lies between $a_i$ and $b_k$, since $\hat{d}_i$ and $\hat{d}_k$ are both decreasing at $q$. Hence, $q$ lies between $a_j$ and $\bar{b}_j$, i.e., $\hat{d}_j$ is decreasing at $q$, as well. We show $\hat{d}_j(x) < \hat{d}_i(x)$ for all $x \in C$, which implies that $\alpha_j$ is irrelevant.

Fig. 9. The constellation from Lemma 5 where $\alpha_i$ and $\alpha_k$ are farthest arcs from $q$ where the farthest distances decreases as $q$ moves in clockwise direction (a). A comparison of the arc distance functions $\hat{d}_i$ and $\hat{d}_j$ reveals that $\alpha_j$ is irrelevant in this case (b).

Consider the difference $\Delta(x) := \hat{d}_i(x) - \hat{d}_j(x)$. We have $\Delta(a_i) = \Delta(q) > 0$, as $\hat{d}_i$ and $\hat{d}_j$ are decreasing with the same slope from $q$ to $a_i$. We have $\Delta(b_i) = \Delta(a_i) + d(a_i, b_i)$, as $\hat{d}_i$ remains constant from $a_i$ to $b_i$ while $\hat{d}_j$ decreases. We have $\Delta(a_j) = \Delta(b_i) + 2d(b_i, a_j)$, as $\hat{d}_i$ increases from $b_i$ to $a_j$ while $\hat{d}_j$ decreases. We continue in this fashion and obtain the following description of $\Delta$.

$$
\begin{align*}
\Delta(a_i) &= \Delta(q) & \Delta(\bar{a}_i) &= \Delta(b_j) \\
\Delta(b_i) &= \Delta(a_i) + d(a_i, b_i) & \Delta(\bar{b}_i) &= \Delta(\bar{a}_i) - d(\bar{a}_i, \bar{b}_i) \\
\Delta(a_j) &= \Delta(b_i) + 2d(b_i, a_j) & \Delta(\bar{a}_j) &= \Delta(\bar{b}_i) - 2d(\bar{b}_i, \bar{a}_j) \\
\Delta(b_j) &= \Delta(a_j) + d(a_j, b_j) & \Delta(\bar{b}_j) &= \Delta(\bar{a}_j) - d(\bar{a}_j, \bar{b}_j)
\end{align*}
$$

The claim follows as the above implies $\Delta(x) \geq \Delta(q) > 0$ for all $x \in C$, due to the symmetries $d(a_i, b_i) = d(\bar{a}_i, \bar{b}_i)$, $d(b_i, a_j) = d(\bar{b}_i, \bar{a}_j)$, and $d(a_j, b_j) = d(\bar{a}_j, \bar{b}_j)$. \qed

Corollary 1. Let $q$ be a point on the cycle of a bead-chain with no overlong arc. The farthest arcs from $q$ that correspond to decreasing/increasing segments of $\hat{D}$ form one consecutive sub-list of the circular list of relevant arcs.

Using Corollary 1 we answer a farthest-arc query from a query point $q$ along the cycle of a bead-chain network without overlong arc as follows. When $\hat{D}$ has a
plateau at \( q \), we report the farthest arcs stored with it; there may be arc one for a high plateau and one arc for a low plateau. When \( D \) has an increasing/decreasing segment at \( q \), we report the farthest arc \( a \) stored with this segment and report farthest arcs as we cycle through the relevant arcs in both directions until we reach the first relevant arc that is no longer farthest from \( q \).

\[ \text{Theorem 2. Let} \ N \text{ be a bead-chain network with} \ n \text{ vertices. There is a data structure with} O(n) \text{ size and} O(n) \text{ construction time supporting} O(k + \log n)-\text{time farthest-point queries on} \ N, \text{ where} \ k \text{ is the number of farthest points.} \]

\text{Proof. Let} \ N \text{ be a bead-chain network with cycle} \ C \text{ and arcs} \ \alpha_0, \alpha_1, \ldots, \alpha_s \text{ where only} \ \alpha_0 \text{ may be overlong. Our data structure for farthest-point queries in} \ N \text{ consists of several smaller data structures. We support queries from} \ C \text{ with two data structures: The first data structure supports farthest-point queries in the parallel-path network} \ \alpha_0 \cup C \text{ to detect farthest points on} \ C \text{ and on the potentially overlong arc} \ \alpha. \text{ The second data structure supports farthest-arc queries in} \ N \setminus \alpha. \text{ As shown in Theorem [1] and Lemma [4]} \text{ both of these structures have linear construction time. For a farthest-point query from} \ q \in C, \text{ we first perform a farthest-distance query from} \ q \text{ in} \ \alpha \cup C \text{ and in} \ N \setminus \alpha_0 \text{ before performing a farthest-point query depending on which sub-network reported the larger value.}

\text{We support queries from an arc} \ \alpha_i \text{ using three data structures: The first data structure supports farthest-point queries in the cycle} \ \alpha_i \cup \beta_i \text{ (or in} \ C \cup \alpha_0 \text{ in case of} \ i = 0). \text{ As our second data structure we re-use the data structure supporting farthest-point queries in} \ N \text{ from the cycle} \ C \text{ from above. The third data structure consists of the partial upper envelope} \ D' \text{ from the proof of Lemma [4]. To answer a query from} \ q \in \alpha_i \text{, we first query from} \ q \text{ with respect to} \ \alpha_i \cup \beta_i. \text{ We distinguish three cases based on the position of} \ q \text{ along} \ \alpha_i \text{ to report any farthest points from} \ q \text{ in} \ N \text{ outside of} \ \alpha_i: \text{ When} \ q \text{ lies between} \ a_i \text{ and} \ b_i \text{ (left case), we report the farthest points from} \ q \text{ in} \ N \setminus \alpha_i \text{ with a query from} \ a_i \text{ in} \ N. \text{ When} \ q \text{ lies between} \ \hat{a}_i \text{ and} \ b_i \text{ (right case), we report the farthest points from} \ q \text{ in} \ N \setminus \alpha_i \text{ with a query from} \ b_i \text{ in} \ N. \text{ When} q \text{ lies between} \ \hat{b}_i \text{ and} \ \hat{a}_i \text{ (middle case), we attempt a query from the unique point} \ q' \text{ on} \ \beta_i \text{ with} d(\hat{b}_i, q) = d(a_i, q). \text{ Since} \ q' \text{ preserves the relative position from} \ q \text{ on} \ \alpha_i, \text{ the query from} \ q' \text{ yields the farthest points from} \ q \text{ in} \ N \text{ outside of} \ \alpha_i \text{ except when} \ q' \text{ has only a single farthest point on} \ \alpha_i. \text{ This occurs when} \ D \text{ has the low plateau of} \ \hat{d}_i \text{ at} \ q'. \text{ Fortunately, we are able to recover the correct answer, since the upper envelope of} \ \hat{d}_i, \ldots, \hat{d}_{i-1}, \hat{d}_{i+1}, \ldots, \hat{d}_s \text{ at} \ q' \text{ coincides with the partial upper envelope} D' \text{ from the proof of Lemma [4].}

\text{Our data structure has} O(n) \text{ size and construction time, since each vertex appears only in a constant number of sub-structures each of which have linear construction time. Every farthest-point query takes} O(k + \log n) \text{ time, because each query consists of a constant number of} O(\log n)\text{-time farthest-distance queries followed by a constant number of farthest point queries only in those sub-structures that actually contain farthest points from the original query.} \]

\footnote{Recall that} D' \text{ was the upper envelope of the functions that result from replacing the low plateaus of} \ \hat{d}_1, \ldots, \hat{d}_s \text{ by extending their increasing/decreasing segments.}

\[ \]

12
4 Abacus Networks

An abacus is a network $A$ consisting of a parallel-path network $N$ with arcs attached to its parallel paths, as illustrated in Fig. 10. Let $P_1, \ldots, P_p$ be the parallel paths of $N$ and let $B_i$ be the $i$-th parallel path with attached arcs.

We split farthest-point queries in an abacus into an inward query and an outward query: an inward query considers farthest points on the chain containing the query point; an outward query considers farthest points on the remaining chains. We first perform the farthest distance version of inward and outward queries before reporting farthest points where appropriate. Figure 11 illustrates how we treat inward and outward queries in the following.

For an inward query from $q$ on chain $B_i$, we construct the bead-chain network $B_i'$ consisting of $B_i$ with an additional edge from $u$ to $v$ of weight $d(u, v)$, as illustrated in Fig. 11a. Since $B_i'$ preserves distances from $A$, the farthest points from $q \in B_i'$ are the farthest points from $q$ among the points on $B_i$ in $A$.

For outward queries in an abacus, we distinguish the same three cases as for parallel-path networks: we are in the left case when every shortest path tree reaches $u$ before $v$, we are in the right case when every shortest path tree reaches $v$ before $u$, and we are in the middle case otherwise. Analogously to Lemma 1, the left case applies when we are within distance $d(u, \bar{v}_i)$ from $u$ and the right case applies when we are within distance $d(v, \bar{u}_i)$ from $v$.

For an outward query from $q \in B_i$ in the left case, $q$ has the same farthest points as $u$ outside of $B_i$. During the construction of the networks $B'_1, \ldots, B'_p$ for inward queries, we determine a list $L_j$ of the farthest points from $u$ in $B'_j$. Similarly to our treatment of the left case for parallel-path networks, we only keep the list achieving the highest farthest distance and the lists achieving the second highest farthest distance. With this preparation, answering the query for $q$ amounts to reporting the entries of the appropriate lists $L_j$ with $j \neq i$. 

![Fig. 10. An abacus with the arcs (colored) attached to its parallel-path network (black).](image-url)
Fig. 11. Inward (a) and outward (b–f) queries for the abacus network from Fig. 10. Inward queries are answered in the bead-chain containing the query (a). Outward queries in the side case are answered with queries from the terminals (b,c). Outward queries in the middle case from arcs are translated to queries from the path (d) and then to queries from a virtual edge (e). From the perspective of the virtual edge, we conceptually collapse all bead-chains of the abacus to support virtual queries (f).
For middle case outward queries, we proceed along the following four steps:
First, we translate every outward query from an arc of $B_i$ to an outward query from the path $P_i$, i.e., we argue that it suffices to consider outward queries from the parallel paths (Fig. 11d). Second, we translate outward queries from $P_i$ to outward queries from a virtual edge $\tilde{e}$ connecting the terminals (Fig. 11e). Third, we speed up queries from the virtual edge by superimposing the data structures for the bead-chains $B_1 \cup \tilde{e}, \ldots, B_p \cup \tilde{e}$, i.e., by conceptually collapsing the parallel chains (Fig. 11f). Finally, we recover the correct answer to the original outward query from the answer obtained with an outward query from the virtual edge.

**Lemma 6.** Let $\alpha$ be an arc in an abacus and let $\beta$ be the other path connecting the endpoints of $\alpha$. For every point $q \in \alpha$ in the middle case, there is a point $q' \in \beta$ such that $q'$ has the same outward farthest points as $q$.

**Proof.** We continuously deform $\alpha$ to $\beta$ maintaining the relative position of $q$ to the endpoints of $\alpha$. The distance from $q$ to all points in the network decreases at the same rate, hence, the outward farthest points remain the same.

We introduce a virtual edge $\tilde{e}$ from $u$ to $v$ of length $w_p$, i.e., the length of the longest $u$-$v$-path $P_p$ in the underlying parallel-path network, as illustrated in Fig. 11c. Let $\bar{u}$ be the farthest point from $u$ on $\tilde{e}$ and let $\bar{v}$ be the farthest point from $v$ on $\tilde{e}$. From Lemma 2, we know that the sub-edge $\bar{u}\bar{v}$ of $\tilde{e}$ has length $d(u,v)$ and, thus, the same length as the sub-path from $\bar{u}$ to $\bar{v}$ on each parallel path $P_i$. We translate an outward query from $q \in P_i$ to a query from the unique point $\hat{q}$ on $\tilde{e}$ such that $\hat{q}$ has the same distance to $\bar{u}$ and to $\bar{v}$ as $q$ to $\bar{u}$ and to $\bar{v}$.

**Lemma 7.** For $q \in P_i$ in the middle case, the farthest points from $q$ in $P_i \cup B_j$ are the farthest points from $\hat{q}$ in $\tilde{e} \cup B_j$ for every $j \neq i$.

**Proof.** We continuously elongate $P_i$ to $\tilde{e}$ maintaining the relative position of $q$ to $u$ and $v$ and, thus, to $\bar{v}$ and $\bar{u}$. At the end of this process $q$ coincides with $\hat{q}$. The distance from $q$ to all points outside of $B_i$ increases uniformly. Hence, the outward farthest points remain the same throughout the deformation.

It would be too inefficient to inspect each bead-chain network $B_j \cup \tilde{e}$ with $j \neq i$ to answer an outward query from $q \in P_i$. Instead, we first determine the upper envelopes of the farthest-arc distances $D_1, \ldots, D_p$ along $\tilde{e}$ in each $B_1 \cup \tilde{e}, \ldots, B_p \cup \tilde{e}$ and then compute their upper envelope $U_1$ as well as their second level $U_2$, i.e., the upper envelope of what remains when we remove the segments of the upper envelope. Computing the upper envelope and the second level takes $O(n \log p)$ time, e.g., using plane sweep. Using fractional cascading, we support constant time jumps between corresponding segments of $U_1$ and $U_2$.

We answer an outward query from $q \in P_i$ in the middle case by translating $q$ to $\hat{q}$. When the segment defining $U_1$ at $\hat{q}$ is from some arc $\alpha$ of $B_j$ with $j \neq i$, then $\alpha$ contains an outward farthest point from $q$. When the segment defining $U_1$ at $\hat{q}$ corresponds to an arc of $B_i$, then we jump down to $U_2$, which leads us to an arc containing an outward farthest point from $q$. We report the remaining arcs with outward farthest points by walking $\hat{q}$ along $U_1$ and $U_2$. In order to skip
long sequences of segments from $B_1$, we introduce pointers along $U_1$ to the next segment from another chain in either direction. Answering outward queries in the middle case takes $O(k + \log n)$ time after $O(n \log p)$ construction time.

**Theorem 3.** Let $N$ be an abacus with $n$ vertices and $p$ chains. There is a data structure of size $O(n)$ with $O(n \log p)$ construction time supporting farthest-point queries on $N$ in $O(k + \log n)$ time, where $k$ is the number of farthest points.

### 5 Two-Terminal Series-Parallel Networks

Consider a two-terminal series-parallel network $N$. By undoing all possible series operations and all possible parallel operations in alternating rounds, we reduce $N$ to an edge connecting its terminals and decompose $N$ into paths that reflect its creation history. The colors in Fig. 1 illustrate this decomposition.

**Lemma 8.** Let $N$ be a series-parallel network with parallelism $p$ and serialism $s$. Identifying the terminals of $N$ and reconstructing its creation takes $O(s + p)$ time.

**Proof.** Recall that series-parallel networks are planar [6]. We maintain a series-parallel network $N$ together with its dual $N^*$ throughout the following reduction process. We keep two arrays $d$ and $d^*$ with $n$ entries each where $d[i]$ stores a list of the vertices of $N$ with degree $i$ and $d^*[i]$ stores a list of the vertices of $N^*$ (faces of $N$) with degree $i$. Each vertex of $N$ and each face of $N$ maintain a pointers to their position in the lists to facilitate constant time deletions.

We proceed in alternating rounds where we either reverse as many series operations or as many parallel operations as possible in each round. To reverse series operations we delete all degree two vertices of $N$. Each deletion changes the degree of two faces of $N$ that were incident to the removed vertex so we move these faces to their new positions in $d^*$. To reverse parallel operations we proceed in the exact same fashion by removing all degree two vertices of $N^*$ and updating $d$ accordingly. We recover the creation history of $N$ by keeping track of when parallel edges were removed during the reversal of a parallel operation. This procedure reduces $N$ to the edge connecting its terminals in $O(s + p)$ steps, since reversing each of the $s + p$ operations takes constant time.  

Once we know the terminals $u$ and $v$ of $N$, we compute the shortest path distances from $u$ and from $v$ in $O(n \log p)$ time.

Consulting the creation history, we determine a maximal parallel-path sub-network $P$ of $N$ with terminals $u$ and $v$. Every bi-connected component $X$ of $N$ that is attached to some path of $P$ between vertices $a$ and $b$ is again a two-terminal series-parallel network with terminals $a$ and $b$. We recurse on these bi-connected components. When this recursion returns, we know a longest $a-b$-path in $X$ and attach an arc from $a$ to $b$ of this length to $P$. The resulting network is an abacus $A$. The abaci created during the recursion form a tree $\mathcal{T}$ with root $A$. Alongside with this decomposition we also create our data structures for the nested abaci.

$\ddagger$ The priority queue in Dijkstra’s algorithm manages never more than $p$ entries.
We translate any query $q$ to a query in the abacus $A$; queries from a bi-connected component $X$ attached to $P$ in $N$ will be placed on the corresponding arc of $A$. Whenever the query in $A$ returns a farthest point on some arc, we cascade the query into the corresponding nested data structure. We add shortcuts to the abacus tree $T$ in order to avoid cascading through too many levels of $T$ without encountering farthest-points from the original query. This way, answering farthest-point queries in $N$ takes $O(k + \log n)$ time in total.

**Theorem 4.** Let $N$ be a two-terminal series-parallel network with $n$ vertices and parallelism $p$. There is a data structure of size $O(n)$ with $O(n \log p)$ construction time that supports $O(k + \log n)$-time farthest-point queries from any point on $N$, where $k$ is the number of farthest points.

6 Conclusion and Future Work

In previous work, we learned how to support farthest-point queries by exploiting the treelike structure of cactus networks. In this work, we extended the arsenal by techniques for dealing with parallel structures, as well. In future work, we aim to tackle more types of networks such as planar networks, $k$-almost trees [8], or generalized series-parallel networks [11].
