Summary. The fine structure in the ampullary region of the vas deferens of the rabbit was observed by scanning and transmission electron microscopy, with emphasis on the occurrence of epithelial spermiophagy. The epithelial cells were cuboidal or low columnar and contained moderately developed organelles. These cells, like luminal macrophages, were found to be not only involved in spermiophagy but also capable of actively taking up latex beads administrated intraluminally. Taking into consideration the previous findings in some other species, the epithelial spermiophagy seems to be a common event in the vas deferens of mammals.

Extensive spermiophagy by the epithelial cells in the terminal region of the vas deferens was first reported by Cooper and Hamilton (1977) in the rat. Later the same phenomenon has been documented in the terminal or ampullary region of the vas deferens of certain mammals including the cat (Murakami et al., 1984a), monkey (Ramos, 1979; Murakami et al., 1981) and also man (Riva et al., 1982; Murakami et al., 1982). In the cat, our observations (Murakami et al., 1984b) confirmed that the epithelial cells in this location reveal phagocytosis of not only spermatozoa but also inert particles as latex beads injected to the lumen. However, it has not yet been determined whether epithelial phagocytosis in the terminal vas deferens is a common event in mammalian species or whether there is species variation in such a cell activity. The epithelium of the ampulla vasis deferentis of the rabbit as studied either by transmission (TEM) or scanning electron microscopy (SEM) or both (Nicander and Schantz, 1961; Kunkelmann and Kühnel, 1984) has not revealed any morphological evidence to support the existence of spermiophagy.

In the present study on the fine structure of the ampulla vasis deferentis of the rabbit with SEM and TEM, special attention was paid to elucidate whether or not the epithelial cells can take in spermatozoa and luminally injected latex beads in a phagocytic manner.

*This investigation was supported in part by a grant from the Ishibashi-Foundation.
MATERIALS AND METHODS

Four adult rabbits weighing approximately 3 kg were used in this study. In two rabbits anesthetized with peritoneally applied Nembutal, 0.5 ml of physiological saline solution containing polyvinyl toluene latex beads (0.3 μm and 1.0 μm in diameter) was injected into the lumen of both scrotal vasa deferentia for 30 min prior to sacrifice. The remaining two animals did not receive such treatment. Then all the animals, under Nembutal anesthesia, were perfused through the ascending aorta with 2.5% paraformaldehyde and 2% glutaraldehyde in cacodylate buffer (pH 7.2). After perfusion, the whole length of the vas deferens from its proximal to ampullary region was taken out and placed in the same fixative for additional 2 hrs. The tissue was washed in cacodylate buffer and postfixed in 2% OsO4 buffered with phosphate (pH 7.2). For TEM study, specimens were dehydrated through a graded ethanol series and embedded in epoxy resin. Thin sections were cut with a diamond knife on a Reichert-Yung microtome, stained with uranyl acetate and lead citrate, and examined with a Hitachi-H 500 TEM. The specimens for SEM were similarly dehydrated through a graded ethanol series, critical point-dried in liquid carbon dioxide, briefly coated with platinum in an ion sputter coater and examined with a Hitachi-HFS2 field-emission SEM. Organic reagents such as acetone, propylene oxide and isoamyl acetate were not used in the present study because they tended to dissolve the latex beads.

RESULTS AND DISCUSSION

The ampulla vasis deferentis of the rabbits dilates as a spindle-shaped enlargement; its cavity consists of one large lumen located centrally and some irregular diverticula arranged radially around it (Fig. 1). Individual diverticula communicate with each other at one end and with the central lumen through a narrow opening at the other. The epithelium lining both the central lumen and the diverticula is composed of low columnar or cuboidal epithelial cells among which a few flattened basal cells are interspaced. The epithelial cells contain moderate numbers of mitochondria, a poorly-developed Golgi complex, many ribosomes, sparse tubules of rough endoplasmic reticulum, abundant microfilaments, a few dense bodies with heterogenous inclusion and infrequent lipid droplets. The large and spherical nuclei with clumps of condensed chromatin occupy the center of the cytoplasm. Granules suggesting a secretory activity cannot be encountered either in the Golgi area or in other regions of the cytoplasm (Fig. 2). The topography and histology of the epithelium of the ampulla vasis deferentis in the rabbit, as just described, are essentially similar to that reported by previous authors (NICANDER and SCHANTZ, 1961; KUNKELMANN and KÜHNEL, 1984).

An SEM view of the apical surface of the epithelial cells is either a flat or slightly bulging hexagonal outline and in the fashion of cobble stone pavement. A few spermatozoa can be seen attaching themselves to the luminal surface of both the central lumen and diverticula (Fig. 3).

A noteworthy observation was the spermiophagy found by SEM in the ampullary epithelial cells in the rabbit. Its incidence is infrequent in the rabbit although quite frequent in the cat and monkey as reported previously (Murakami et al., 1981, 1984a). Spermatozoa are trapped by pseudopod-like flaps arising from the apical surface of the epithelial cells as shown in Figures 4 and 5. In the rabbit the phagocytosis of spermatozoa begins primarily at their head, while it may start not only at the head but also at the tail of spermatozoa in the monkey and man (Murakami et al., 1981; Riva et al., 1981), and even at the middle area in the cat (Murakami et al., 1984a).

In thin sections, spermatozoa at various stages of disintegration following phagocytosis were observed within phagocytic vacuoles in the cytoplasm of the epithelial cells (Fig. 6). The fate of these ingested spermatozoa is essentially the same as that described in the epithelium of the same region of the vas deferens of the cat (Murakami et al., 1984a) and the rat (Cooper and Hamilton, 1977). Sporadic spermiophagy by epithelial cells has already been reported in other parts of the male reproductive system such as the seminiferous tubules (Dym, 1974; Nykänen, 1979), rete testis (Burgos and

**Fig. 3.** Overview of the luminal surface of the central lumen. The luminal surface of the epithelial cells is flat or slightly protruded and covered by stubby microvilli. Round or slit-like apertures are openings to the diverticula. A few spermatozoa are also visible on the luminal surface. ×1,200

CAVICCHIA, 1975; HOLSTEIN, 1978; GOYAL, 1982), efferent ductules (GOYAL, 1982), ejaculatory duct (Cossu et al., 1983) and seminal vesicles (RIVA et al., 1981) in some mammals including man.

In the lumen of the ampulla vas deferentis, macrophages are often seen attached to the apical surface of the epithelial cells, and many of them are loaded with a cluster of spermatozoa (Fig. 7). Spermiophagy by luminal macrophage has recently been documented as occurring normally along the entire length of the male reproductive tract including the vas deferens in some mammals (COOPER and HAMILTON, 1977; KENNEDY and HEIDGER, 1979; HOLSTEIN, 1978; MURAKAMI et al., 1978, 1984a; GOYAL, 1982).

SEM micrographs of the animals with latex beads injected into the vas deferens

demonstrate numerous beads located on and among the microvilli of the epithelial cells. Some of the beads are observed to be captured singly or in groups by cytoplasmic pseudopods extended from the epithelial cells (Fig. 8) as has been seen in the cat (Murakami et al., 1984b).

In TEM, engulfed latex beads were confirmed to be either enclosed in phagocytic vacuoles or embedded within lysosomal dense bodies in the cytoplasm of the epithelial cells (Fig. 9). Besides the epithelial cells, luminal macrophages were also actively taking up the latex beads injected, though this is not illustrated here.

The results presented in this study clearly indicate that the epithelial cells of the ampulla vasis deferentis of the rabbit are capable of ingesting spermatozoa and even latex beads at variance with the finding of the previous authors (Nicander and Schantz, 1961; Kunkelmann and Kühnel, 1984), who failed to detect spermiophagy by the epithelial cells in the ampullary region of rabbit vas deferens. This phenomenon occurring in the vas deferens is probably common in mammalian species, because our unpublished observation indicate that the dog vas deferens also is capable of taking up spermatozoa and latex beads in the fashion of epithelial phagocytosis. The functional significance of the epithelial phagocytosis is unknown, but it is conceivable that the epithelial cells act to dispose damaged or excess spermatozoa passing through the lumen. The same cells also take up latex beads which are foreign in nature.
