B-meson production at forward and backward rapidity in p + p and Cu + Au collisions at $\sqrt{s_{NN}} = 200$ GeV
Heavy quarks (charm and bottom quarks in the context of this work) are a powerful tool to investigate initial-state effects on gluons in nuclear collisions. Initial-state nuclear effects can alter the number of heavy quarks produced compared to extrapolations from collisions. Once produced, however, the number of heavy quarks is preserved in strong interactions in the medium.

The fraction of $J/\psi$ mesons which come from B-meson decay, $F_{B\rightarrow J/\psi}$, is measured for $J/\psi$ rapidity $1.2 < |y| < 2.2$ and $p_T > 0$ in $p + p$ and Cu+Au collisions at $\sqrt{s_{NN}} = 200$ GeV with the PHENIX detector. The extracted fraction is $F_{B\rightarrow J/\psi} = 0.025 \pm 0.006$ (stat) $\pm 0.010$ (syst) for $p + p$ collisions. For Cu+Au collisions, $F_{B\rightarrow J/\psi}$ is $0.094 \pm 0.028$ (stat) $\pm 0.037$ (syst) in the Au-going direction ($-2.2 < y < -1.2$) and $0.089 \pm 0.026$ (stat) $\pm 0.040$ (syst) in the Cu-going direction ($1.2 < y < 2.2$). The nuclear modification factor, $R_{Cu/Au}$, of B mesons in Cu+Au collisions is consistent with binary scaling of measured yields in $p + p$ at both forward and backward rapidities.

The fraction of $J/\psi$ mesons from $B$-meson decays from prompt $J/\psi$s is nearly constant over all transverse momenta, allowing for the direct extraction of momentum integrated $b$-quark yields, corresponding to the number of $b$ quarks in the rapidity acceptance. With these yields, we can verify whether initial-state effects are relevant to $B$-meson production in nucleus + nucleus collisions.

The only known source of nonprompt $J/\psi$ is production via $B$-meson decay [3], which has a typical decay time $\tau_0 \sim 1.5$–1.6 ps [4]. The constituent bottom quarks have mass $m_b \sim 4.5$ GeV/c$^2$ and are created from processes such as gluon fusion ($gg \rightarrow Q \bar{Q}$), flavor excitation where heavy quarks ($Q$) from the nucleon wave function scatter with gluons ($Qg \rightarrow Qg$), and gluon splitting ($gg \rightarrow Q \bar{Q}g$) [5,6]. Gluon-gluon fusion and flavor excitation are equally dominant, whereas the gluon splitting contribution is small at $\sqrt{s} = 200$ GeV according to PYTHIA8 hard scattering simulations [7].

Initial-state effects on the precursor gluons, before their hard scattering, include coherent multiple scattering, also called dynamical shadowing [6], incoherent multiple scattering [8,9], initial state energy loss [10], and saturation of small momentum fraction $x$ gluons [11]. Nuclear parton distribution functions, extracted from deep inelastic scattering and Drell-Yan experimental data, such as EPS09 [12] and impact-parameter-dependent EPS09s [13], indicate a pattern of suppression for small-$x$ gluons and an enhancement separation of $J/\psi$s from $B$-meson decays from prompt $J/\psi$s.

I. INTRODUCTION

Heavy quarks (charm and bottom quarks in the context of this work) are a powerful tool to investigate initial-state effects and quark-gluon plasma (QGP) medium formation in heavy ion collisions. Initial-state nuclear effects can alter the number of heavy quarks produced compared to extrapolations from $p + p$ collisions. Once produced, however, the number of heavy quarks is preserved in strong interactions in the medium.

Final-state effects, such as energy loss in the QGP [1,2], can only modify the momentum distribution of these quarks and open heavy mesons. On the other hand, the number of prompt $J/\psi$ is not expected to be preserved in the medium because of the low $c\bar{c}$ binding energy, which can allow the $J/\psi$ to be broken by medium interactions.

The $B$ mesons, which decay to $J/\psi$ and subsequently decay into dimuon pairs, represent a relatively clean channel to extract $b$-quark yields. At the Relativistic Heavy Ion Collider (RHIC), the PHENIX forward silicon-vertex detector (FVTX) along with the central silicon-vertex detector (VTX) provide the ability to measure precise event vertex positions as well as displacement of the decay muon trajectories from the reconstructed event vertex. This allows for the statistical

of intermediate to large-$x$ gluons. Semileptonic decays of particles carrying heavy flavor and produced inclusively in $d + Au$ collisions at $\sqrt{s_{NN}} = 200$ GeV [14,15] indicate yield suppression at forward rapidity, where Bjorken $x \sim 5 \times 10^{-3}$ gluons dominate. The same analysis also revealed a clear yield enhancement at mid- and backward rapidity, where gluons with fractional momentum $0.05 \lesssim x \lesssim 0.2$ are dominant. A similar enhancement was observed in the measurements of $D$ mesons in $d + Au$ at midrapidity [16].

Asymmetric Cu+Au collisions have the advantage of being a relatively large system that can access different $x$ regions at positive and negative rapidities. Studies in these collisions provide a powerful test of how initial-state effects observed in small systems, such as $p + A$, can be projected in large heavy ion collisions. In the PHENIX muon arms, positive rapidity corresponds to the Cu-going direction, probing small-$x$ in the Au nucleus and large-$x$ in the Cu. Negative rapidity covers the Au-going direction, probing small-$x$ in the Cu nucleus and large-$x$ in the Au. Initial state parton distribution modifications are predicted to be stronger in the Au nucleus [17]. If these modifications have the same pattern as seen in $p(d) + A$ collisions, they may cause suppression in the Cu-going (positive rapidity) direction and enhancement in the Au-going direction. Initial-state energy loss [18] also results in larger suppression at positive rapidity.

In this study, we quantify the fraction of muons from the decay of nonprompt $J/\psi$ in $p + p$ and Cu+Au collisions at $\sqrt{s_{NN}} = 200$ GeV using the PHENIX muon arms measuring in the rapidity range $1.2 < |y| < 2.2$. The nonprompt fractions are then used to compute the nuclear modification of $B$ mesons in Cu+Au collisions. This result uses the capability to measure the approach between muons and the collision vertex using the FVTX [19]. Section II describes the experimental apparatus and the data set. Section III describes the data selection, backgrounds, and defines the distance of closest approach (DCAR). Section IV describes the simulation setup used to obtain the DCAR distribution profiles. The fit to the real data distance of closest approach distributions is detailed in Sec. V. Systematic uncertainties are discussed in Sec. VI. Results and interpretations are presented in Sec. VII.

II. EXPERIMENTAL APPARATUS AND DATA SET

This analysis was performed using data sets obtained with the PHENIX detector (Fig. 1) at the Relativistic Heavy Ion Collider during the 2015 $p + p$ and 2012 Cu+Au $\sqrt{s_{NN}} = 200$ GeV runs. Each collision was identified by the north and south beam-beam counters (BBC) which each comprise 64 quartz radiators instrumented with mesh dynode PMTs covering charged particles in the pseudorapidity region $3.0 < |\eta| < 3.9$ and with time resolution of $\sim 50$ ps. A fast online collision $z$ vertex can be determined from the difference between the average north and south arrival times. A minimum-bias (MB) event is triggered by two or more hits in each BBC and a measured vertex position $|z_{vtx}| \lesssim 10$ cm, and results in an acceptance of $93 \pm 3\%$ of the total Cu+Au cross section. For $p + p$ collisions, one or more hits are required in each BBC for the MB trigger, and $55 \pm 5\%$ of the total inelastic cross section is accepted. This analysis also used a sample of dimuon triggered events (MUIDL1_2D), which required two roads of hits found in the Iarocci tubes in the muon identifiers (MuID), including at least one road that reached the most downstream tubes.

A. PHENIX muon spectrometers

Each muon spectrometer covers a pseudorapidity range of $1.2 < |\eta| < 2.2$ and $2\pi$ in azimuth. Each spectrometer comprises hadron-absorber material, muon trackers (MuTr) inside a conical-shaped magnet, and a MuID. The first layer of hadron absorber, placed between the FVTX and the MuTr, comprises 19 cm of copper, 60 cm of iron from the central magnet, and 36.2 cm steel, corresponding to a total of 7.2 nuclear interaction lengths. This material absorbs pions and kaons emitted into the acceptance of the muon arms. The muon magnet system provides a radial field inside the MuTr volume of approximately $\int B \cdot dl = 0.72$ T m at 15 degrees from the beam axis, bending particles in the azimuthal direction.

Tracking and momentum measurements are performed by the MuTr, which comprises 8 octants of cathode strip chambers distributed in each of three $z$ stations. The first two stations have three sensitive planes each, and the fastest station from the interaction region has two sensitive planes. Each plane contains two cathode readout strip planes with varying stereo angle orientations among the planes in the station to provide measurements in two spatial dimensions. The momentum resolution achieved by the MuTr is $\delta p/p \approx 0.05$ for a typical muon from $J/\psi$ decays.

The north and south MuID systems are located downstream of the MuTr and comprise five absorber plates totaling 4.8 (5.4) nuclear interaction lengths in the south (north) arm. Two Iarocci tube planes with vertical and horizontal orientations distributed in six individual panels are placed after each of the five absorber gaps. Pion and kaon rejection after all absorber material is larger than a factor of 250. Only muons with momentum $>3$ GeV/c are able to penetrate all absorbers. Recorded hits in the tubes are used to reconstruct roads which are used in the MUIDL1_2D trigger and in full muon track reconstruction. Technical details of the muon arms can be found in Refs. [20,21].

FIG. 1. Schematic view of the detector apparatus along with an illustrated dimuon and a hadron stopping in one of the muon identifiers (MuID) gaps.
TABLE I. Summary of FVTX geometry.

| Parameter                        | Value                      |
|----------------------------------|----------------------------|
| Mean z position of discs [cm]    | ±20.1, ±26.1, ±32.2, ±38.2 |
| φ segmentation each disk         | 48 wedges × 2 columns      |
| Inner radius                      | 4.4 cm                     |
| Strip pitch                       | 75 μm                      |
| Strip length                      | 3.4 mm to 11.5 mm          |
| Total number of strips            | 1.08 M                     |
| Silicon thickness                 | 320 μm                     |

Particles produced at the primary vertex cross ~7.2 interaction lengths of absorber before reaching the first MuTr station located at z = ±190 cm. Due to multiple scattering in the absorber, the projection of tracks reconstructed in the MuTr to the FVTX has a standard deviation radius of 3 cm. The FVTX helps track these particles from the absorber to the vertex point.

A precise vertex measurement is provided offline (Sec. III C) by the central arm vertex detector (VTX) and the FVTX. The VTX [22,23] is a silicon detector with four radial layers placed at 2.6, 5.1, 11.8, and 16.7 cm from the z axis, covering 2 × Δφ ≈ 1.6π and |z_{vtx}| < 10 cm. The innermost two layers have pixel segmentation of Δφ × Δz = 50 μm × 425 μm and the two outer layers comprise stripixels with an effective pixel size of 80 μm in RΔφ and 1 mm in z.

The FVTX is a silicon detector installed in 2012 to precisely measure the radial distance of closest approach (DCAR) of extrapolated particle trajectories to the collision vertex (Sec. III D), allowing statistical separation between prompt muons and muons from the decay of long-lifetime particles. Geometrical characteristics of the FVTX are listed in Table I. More technical details concerning the FVTX detector can be found in Ref. [19].

Tracks reconstructed in the silicon system are required to have at least three hits in different FVTX disks and/or VTX pixel layers (seen as half-cylinders in Fig. 2).

FIG. 2. Schematic view of the west VTX and north-west arm FVTX detectors used in this analysis.

magnetic field in the region of the FVTX is primarily in the z direction, resulting in only a very small bending of tracks in the φ direction. Therefore, the FVTX cannot measure particle momentum, which can be reconstructed only if the FVTX track is associated to a MuTr track.

B. Data set and quality assurance

Only collisions with a vertex determined by the VTX and FVTX within z = ±10 cm from the nominal interaction point are selected. Collisions where the vertex determination (Sec. III C) has an uncertainty larger than 500 μm (200 μm) are also rejected in p + p (Cu+Au) data. The fraction of collisions within the vertex range used in this analysis is 14% in p + p and 18% in Cu+Au. Only MB triggers or MUIDLL1_2D triggers in coincidence with a MB trigger (MUIDLL1_2D&MB) were analyzed. In p + p the number of analyzed events in the selected vertex region is 3.4×10^11, corresponding to an integrated luminosity of ∫ Ldt = 14.8 pb⁻¹. In Cu+Au 5.7×10^10 MB and 284×10^6 MUIDLL1_2D&MB events were analyzed in the selected vertex range. The MB trigger is sensitive to σ_{Cu+Au} = 5.23 ± 0.15 b of the total Cu+Au cross section, according to Glauber calculations reported in Ref. [17]. Therefore, the Cu+Au events used in this analysis correspond to ∫ Ldt = 1.0 nb⁻¹, or the p + p equivalent of 11.8 pb⁻¹.

The run-by-run average DCAR (described in Sec. III D) measured for of all charged particles by the FVTX was found to be stable throughout the data collection period in the Cu+Au run. For the case of p + p collisions, ~10% of data are rejected due to instabilities of the measured DCAR.

III. DATA SELECTION AND HOW TO OBTAIN THE DISTANCE OF CLOSEST APPROACH DISTRIBUTIONS

B-mesons have a mean decay length cτ_0 ~ 450 μm, a scale measurable by precision vertex detectors. At large rapidity the momentum boost γ = √(p_T^2 + p_T^2 + m^2)/m to the decay length is larger than at midrapidity (p_T ~ 0), allowing B-meson identification via nonprompt decays even at zero transverse momentum.

Typically, the fraction of B-meson decays in J/ψ samples (here defined as F_{B→J/ψ}) is determined by measuring the vertex given by the intersection of the two muon trajectories in the dimuon pair. This approach is not used in this analysis because: (1) the J/ψ dimuon vertex cannot be precisely determined because of the limited φ resolution of the FVTX; (2) a fraction of the sample of J/ψ decays would be lost in the sample when one of the muons reconstructed by the MuTr does not match to the FVTX.

In this analysis, the J/ψ decay is identified by the dimuon invariant mass of selected MuTr + MuID tracks. In a second step, muon candidates from the identified J/ψ decay that have matching FVTX tracks are selected. The radial distance of closest approach DCAR (Sec. III D) is determined for combined FVTX + MuTr + MuID tracks after quality cuts. The following sections detail how the sample is selected, how the backgrounds are treated, and how DCAR is defined.
A. Selection of \( J/\psi \) candidates

Single muon candidates are MuTr tracks that are associated to MuID roads (Sec. II A). The MuTr track is required to have at least 11 out of a maximum of 16 hits in different cathode planes, and the fitted track should return a \( \chi^2/NDF < 10 \), cut based on the distribution obtained from simulated muons which also accounts for tracks crossing malfunctioning channels in the MuTr. Because a track is required to cross all absorbers, only muons with a total reconstructed momentum larger than 3 GeV/c are accepted. The MuID roads are required to have at least 6 out of a possible 10 hits in different tube planes, including a hit in one of the planes located behind the last MuID absorber. Three standard deviation cuts are applied to the distance and angle between the MuTr track and the MuID road projections at the first MuID gap. Dimuon pairs formed from MuTr + MuID selected muons are required to have an opening angle larger than 45° if the dimuon \( p_T \) is smaller than 5 GeV/c. Implementation of this cut helps remove contributions from ghost tracks. A fit involving the geometric average between same-event like-sign sources determined from mixed-event dimuons and normalized by the correlated background functional form of \( f_{\text{cont}}(m) \) accounts for an exponential behavior at low mass and a power-law behavior at high mass, verified in PYTHIA8 simulation of \( c\bar{c} \) and \( b\bar{b} \) pair production. The free parameters in the fit are \( N_{\text{cont}}, f_{J/\psi}, N_\psi, c_{\text{mix}}, \lambda_{\text{mix}}, \text{and } \lambda_{\text{mix}} \). Fitting constrains are applied to \( c_{\text{mix}}, \lambda_{\text{mix}}, \text{and } \lambda_{\text{mix}} \) according to a \( f_{\text{cont}}(m) \) fit to correlated-like-sign dimuon mass distribution in the same mass range. Table II also shows the extracted fractions of correlated background in the \( J/\psi \) mass region:

\[
f_{\text{cont}} = \int_{m=2.8}^{3.5} dm N_{\text{cont}} f_{\text{cont}}(m) \quad (3)
\]

B. FVTX-MuTr track association

Requirements for stand-alone FVTX track selection include a minimum of three hits in different FVTX or VTX planes. The analysis requires a FVTX track has a \( \chi^2 \) probability (\( p \) value) larger than 5%. The track quality selection keeps 95% of the true tracks according to simulations. FVTX-MuTr track matching is performed as follows:

1. MuTr and FVTX tracks are projected to three \( z \)-plane locations: (1) the fourth FVTX disk from the vertex, (2) the middle of the absorber materials in front of the MuTr, and (3) the first MuTr station. Radial \( R \) and azimuthal \( \phi \) position and momentum projections, and uncertainties \( \sigma_{R_{\text{FVTX-MuTr}}}, \sigma_{\phi_{\text{FVTX-MuTr}}}, \sigma_{R_{\text{FVTX-MuTr}}}, \sigma_{\phi_{\text{FVTX-MuTr}}} \) are calculated for each FVTX and MuTr track using the GEANTE Kalman Filter algorithm [24], taking into account the detector geometry, the amount of absorber material, and the magnetic field map. The momentum magnitude used for FVTX track projections is taken from the associated MuTr track.

2. A combined FVTX + MuTr track \( \chi^2 \) is calculated for each association from individual \( \chi^2_{\text{FVTX}} \) and \( \chi^2_{\text{MuTr}} \) track qualities and FVTX-MuTr projection residuals in the tree planes in an approximation considering the correlation between residuals in different planes is small:

\[
\chi^2 = \chi^2_{\text{FVTX}} + \chi^2_{\text{MuTr}} + \chi^2_{\text{match}}
\]

\[
\chi^2_{\text{match}} = \sum_{i=1}^{3} \left( \frac{(R_{\text{FVTX-MuTr}} - R_{i})^2}{\sigma R_{i}^2} + \frac{(\phi_{\text{FVTX-MuTr}} - \phi_{i})^2}{\sigma \phi_{i}^2} \right) + \left( \frac{(p_{\text{FVTX-MuTr}} - p_{i})^2}{\sigma p_{i}^2} \right) + \left( \frac{(p_{\text{FVTX-MuTr}} - p_{i})^2}{\sigma p_{i}^2} \right)
\]

where \( p_{i} \text{FVTX} \) and \( p_{i} \text{MuTr} \) are just track directions determined by the FVTX.

3. Only FVTX-MuTr combined tracks with \( \chi^2/NDF < 6(3) \) are accepted for further analysis in \( p + p \) (Cu+Au) data.

4. In the \( p + p \) analysis, at least one VTX hit is required for tracks inside the VTX acceptance to reduce effects.
FIG. 3. The dimuon mass distributions in $p+p$ (a)–(f) and Cu+Au (g)–(l) collisions. The mass distribution along with mixed-event dimuons which account for the combinatorial background is shown in panels (a), (b), (g), (h). The distribution after removal of the combinatorial background is shown in panels (c), (d), (i), (j). The lines represent the Eq. $(2)$ components fit to the data points. Panels (e), (f), (k), (l) show the pull between data and fit.

from additional material that was installed just before the 2015 run between the VTX and FVTX.

FVTX-MuTr track mismatches can occur if MuTr tracks are projected onto a region where the FVTX is not active. These MuTr tracks tend to incorrectly associate with tracks in neighboring live regions which can distort the DCAR distributions. Fiducial cuts were applied to remove MuTr track projections onto nonactive $\phi$ regions in the FVTX and their edges to minimize these mismatches. Edge effects are further reduced by requiring the azimuthal residual between the FVTX and MuTr track projections is no larger than

064901-7
used in the DCAR distributions to extract the correct FVTX associations passing matching criteria (not just the best) are the displacement will correspond to a background particle and not track from the candidate muon and an FVTX track from an the true particle (filled circle).

We determined that 65% of MuTr tracks in Cu+Au collisions find more than one potential FVTX track association passing the \( \chi^2 \) quality and the matching criteria described above (Fig. 4), whereas the probability of having more than one association is about 15% in \( p+p \) collisions. Because of this small fraction, the \( p+p \) analysis uses only the best matching. The multiple associations are pronounced in central Cu+Au events because of the large FVTX track density, and for MuTr tracks with small momentum where projection uncertainties are larger because of the estimated multiple scattering in the absorber. In \( B \to J/\psi \to \mu\mu \) events, the best \( \chi^2 \) association has a chance to happen between a MuTr track from the candidate muon and an FVTX track from an underlying event particle. In this situation, the measured vertex displacement will correspond to a background particle and not the \( B \)-meson decay. In the Cu+Au analysis, all FVTX-MuTr associations passing matching criteria (not just the best) are used in the DCAR distributions to extract the correct FVTX and MuTr track associations. The contribution of mismatches to the track associations is then determined from event mixing, where MuTr tracks from one collision event are mixed with FVTX tracks from another event. Collisions are categorized in 10 FVTX track multiplicity and 200 \( z \)-vertex classes. The number of classes was chosen as the minimum number for which there was no observed change in the DCAR distributions of simulations embedded in real data. MuTr tracks are mixed only with FVTX tracks belonging to the same collision event category. DCA distributions from mismatches are normalized by the relative FVTX track densities between same-event and mixed-event associations:

\[
\frac{N_{\text{FVTX tracks in same event}}} {N_{\text{FVTX tracks in mixed events}}}
\]

The number of mixed-event FVTX-MuTr associations is arbitrarily chosen to be five times larger than in same events to reduce background statistical fluctuations. The normalization \( N_{\text{mis}} \) was tested with entire PYTHIA8+GEANT4 events containing prompt \( J/\psi \) and \( B \to J/\psi \) embedded in real data, where the DCAR distributions, after subtracting the normalized, event-mixed mismatch tracks, show excellent agreement with DCAR distributions not embedded in real data.

### C. Primary vertex determination

The \( p+p \) (Cu+Au) collision events are distributed in a volume, \( \sigma_\chi \times \sigma_\phi \times \sigma_z \), of approximately 130 \( \mu m \times 130 \mu m \times 40 cm \) (90 \( \mu m \times 90 \mu m \times 40 cm \)) centered within the PHENIX detector. Collisions within \( z = \pm 10 cm \) produce charged particle tracks in the nominal VTX and FVTX acceptance where the tracking can be utilized to precisely determine the collision point. The primary vertex location is found by the minimization of the squared impact parameter for the collection of reconstructed charged particle tracks found in the VTX and the FVTX. In Cu+Au, bias created by tracks with off-vertex decay points is negligible due to the large number of particles created in the collisions of large nuclei and limits on the impact parameter cluster sizes used during the fitting procedure. In Cu+Au, the final primary vertex position is determined by a three dimensional minimization on an event-by-event basis. The majority of the position information in the minimization comes from tracklets within the VTX layers due to this detector’s fine azimuthal segmentation of 50 \( \mu m \), short projection length of \( \sim 2.6 \) cm, and typically large impact angles between reconstructed tracks. The event multiplicity is the key factor driving variance in the vertex resolution,

\[
\sigma_{\text{VTX}} = \sqrt{\sigma_{\text{VTXx}}^2 + \sigma_{\text{VTxy}}^2 + \sigma_{\text{VTxz}}^2},
\]

where the \( \sigma_{\text{VTXx}}, \sigma_{\text{VTxy}}, \) and \( \sigma_{\text{VTxz}} \) vertex uncertainties are obtained event-by-event from the vertex minimization procedure. The vertex uncertainty is determined from independent measurements in north, south, east and west parts of the VTX and FVTX detector. A check of these uncertainties is performed with detector simulation, using HIJING [25] and PYTHIA8 generated events. The \( \sigma_{\text{VTX}} \) vertex resolution varies between 30 \( \mu m \) (central collisions) and 200 \( \mu m \) (peripheral collisions) in Cu+Au collisions. Due to the low multiplicity in \( p+p \) collisions, the average \( x \) and \( y \) beam position in

### TABLE III. List of vertex position requirements for event selection.

| Requirement                  | Cut                  |
|------------------------------|----------------------|
| \( z \) vertex position range | \( |z| < 10 cm \) |
| Vertex resolution in \( p+p \) | \( \sigma_z < 500 \mu m \) |
| Vertex resolution in Cu+Au   | \( \sqrt{\sigma_x^2 + \sigma_y^2 + \sigma_z^2} < 200 \mu m \) |
FIG. 5. Visual definition of the displaced vertex DCA\textsubscript{R} used in this analysis: (a) 3D, (b) r-z, and (c) x-y views. The collision point VTX is at the origin in this view for simplicity.

D. Distance of closest approach measurement

The combined FVTX + MuTr track is projected to a plane perpendicular to the z axis and placed at the measured z position of the collision point. The displaced vertex vector $\vec{P}_{\text{vtx}}$ is defined by the track projection $(x_{\text{track}}, y_{\text{track}}, z_{\text{vtx}})$ and the collision point $(x_{\text{vtx}}, y_{\text{vtx}}, z_{\text{vtx}})$ as illustrated in Figs. 5(a) and 5(c). This projection is not precise in the $\phi$ direction because of the coarse segmentation of the FVTX in this direction, so the radial projection is used in this analysis, where the FVTX has the best segmentation. In Fig. 5 the radial axis $\vec{R}$ is defined by the track projection at the first FVTX station $(x_{\text{FVTX1}}, y_{\text{FVTX1}}, z_{\text{FVTX1}})$ and the z axis $(0, 0, z_{\text{FVTX1}})$. The precise displacement vertex, which we call the radial distance of closest approach at the vertex plane DCAR is a projection of the vector $\vec{P}_{\text{vtx}}$ on the radial direction $\vec{R}$:

$$\text{DCAR} = \vec{P}_{\text{vtx}} \cdot \frac{\vec{R}}{|\vec{R}|}.$$

Figure 5(b) shows a two-dimensional projection on the r-z plane of the track. The extension of the DCAR distribution depends on the decay length of the parent particle and the rapidity difference between the parent particle and the muon. Figure 6 shows the shape of DCAR distributions of muons from simulated $B \to J/\psi$ and prompt $J/\psi$ decays thrown in the detector response simulation. Negative DCAR (where $\vec{P}_{\text{vtx}}$ and $\vec{R}$ have opposite directions) is larger for long range decays, producing an asymmetric DCAR distributions for muons from heavy flavor decays which facilitates their separation from other contributions from prompt particles during the fitting procedure.

E. Backgrounds in the DCAR distributions

The DCAR distributions comprise MuTr tracks, from dimuons in the $J/\psi$ mass region, which are associated with one or more FVTX tracks. Each FVTX + MuTr association counts in the DCAR distributions. There are two significant sources of uncorrelated background in the DCAR distributions: (1) combinatorial background described in Sec. IIIA in the $J/\psi$ mass region, corresponding to dimuons which are not from $J/\psi$ decays; and (2) FVTX-MuTr mismatches described in Sec. IIIB corresponding to MuTr tracks from $J/\psi$ decays but associated to the wrong FVTX track. Figure 7 shows the contribution of these backgrounds, extracted using the techniques described above, in the raw DCAR distribution obtained in both arms. The combinatorial background distribution is obtained from mixed-event dimuons, and the mismatch contribution is determined from event mixed MuTr-FVTX associations. Statistical fluctuations are reduced by obtaining five times as many mixed-event pairs and misassociations than in same-event backgrounds. The normalization of these two distributions was explained in Secs. IIIA and IIIB. According to the distributions shown in Fig. 7, most background...
The detector response to prompt decays, such as muons from prompt $J/\psi$, is estimated using prompt hadrons (pions, kaons, and protons) generated by the PYTHIA8 event generator in MB mode and a GEANT4-based detector simulation package [26]. Several dead channel configurations are used to account for run-by-run detector acceptance fluctuations. This procedure was found to be crucial to simulate remaining edge effects (Sec. III B) and degradation of VTX-FTX track quality, which can potentially produce long tails in the measured DCAR $(d)$. 

The DCAR line shape of correlated background contributions from $c\bar{c}$ and $b\bar{b}$ is obtained from simulation and discussed in Sec. IV B.

**IV. SIMULATION**

In this section we describe how the DCAR line shape of each dimuon source in the $J/\psi$ mass region is obtained from simulation.

**A. Detector response of prompt particles**

The detector response to prompt decays, such as muons from prompt $J/\psi$, is estimated using prompt hadrons (pions, kaons, and protons) generated by the PYTHIA8 event generator in MB mode and a GEANT4-based detector simulation package [26]. Several dead channel configurations are used to account for run-by-run detector acceptance fluctuations. This procedure was found to be crucial to simulate remaining edge effects (Sec. III B) and degradation of VTX-FTX track quality, which can potentially produce long tails in the measured DCAR distributions. The simulated GEANT4 signals from all generated hadrons in a single PYTHIA8 event are embedded in real data to account for occupancy and accidental hit-track-association effects in the DCAR measurement. All particles generated by the detector simulation are shifted by $(\delta x, \delta y, \delta z)$, where each of the coordinates is a common Gaussian random number centered at the vertex position measured in the real data event and with a width determined from the vertex uncertainty of the real event. The simulated particles are embedded in the reconstructed event, including the simulated hits and the entire real data signal in the event, is then performed in the same manner as with real data.

Additional smearing and offsets are needed in the simulated DCAR to account for irreducible detector misalignments, additional smearing of the primary vertex resolution that is not accounted for in the simulations, and any missing materials in the simulation that could be a multiple scattering source between the interaction region and the last FVTX plane. The measured DCAR resolution depends on (1) the vertex uncertainty $\sigma_{\text{vtx}}$ defined in Eq. (6); (2) a momentum-independent parameter $\sigma_a$, which represents the sum of the detector resolution contributions to the DCAR resolution; and (3) a multiple scattering term $\sigma_b$ in the VTX and FVTX material which introduces the momentum dependence in the resolution:

$$\sigma_{\text{DCAR}}(p, \sigma_{\text{vtx}}) = \sqrt{\sigma_{\text{vtx}}^2 + \sigma_a^2 + (\sigma_b/p)^2}. \quad (8)$$

Particles that stop at the third absorber plane in the MuID comprise mainly prompt light hadrons and $\sim 7\%$ contribution from hadron $\to \mu$ decays according to PYTHIA8+GEANT4 simulation. This sample provides a relatively clean selection of prompt particles which can be used to compare DCAR spectra between simulation and real data. The DCAR distributions from the measured prompt hadrons are compared to simulated hadrons, and small smearing corrections are added to the simulated spectra until they match the real data spectra.

For real data and simulations, the $\sigma_{\text{vtx}}$ value is set according to the event-by-event vertex resolution that is provided by the vertex finding code. The fit parameters $\sigma_a$ and $\sigma_b$ are extracted from the real data distributions, and the simulated data has additional smearing added until the distributions produce the same $\sigma_a$ and $\sigma_b$ fit results. An additional smearing of $70(110) \mu$m was found to be necessary in the $p+p$ (Cu+Au) setup. After tuning the simulation, the DCAR distribution of simulated hadrons stopping in the MuID is weighted according to the momentum distribution of real data stopped hadrons.

Figure 8 shows the DCAR distribution of these prompt hadrons in real data compared to PYTHIA8-generated hadron events, which have had tuned smearing parameters added. Figure 8 also shows the final fit parameters $\sigma_a$ and $\sigma_b$ for each of the north (positive rapidity) and south (negative rapidity) arms. Although the material present in the north and south arms is nominally identical, the momentum-dependent

![Graph](image-url)
resolution parameter \( \sigma_0 \) is found to be different for the two arms in the Cu+Au data set. The reason for this is that the vertex distribution for BBC-triggered events in Cu+Au events was found to be highly skewed toward the north arm, given the collision species asymmetry. Because of this, FVTX tracks had on average a shorter projection to the vertex for tracks in the north arm than in the south arm, resulting in a smaller contribution to the DCAR resolution from multiple tracks in the north arm than in the south. Long tails in the DCAR distribution contain part of the light hadron decay contribution but are mostly dominated by accidental hit-track associations, which are reasonably well reproduced by the embedded simulation in the DCAR range used in this analysis.

### B. Prompt \( J/\psi \) and heavy flavor decay simulations

Prompt \( J/\psi \) and \( B \to J/\psi \) decays are generated using the PYTHIA8 event generator; open heavy flavor from \( c \bar{c} \) and \( b \bar{b} \) processes are produced with leading order processes (gluon fusion) and the CT10 parton density distribution functions [27]. All particles generated in the \( B \to J/\psi \) or prompt \( J/\psi \) event are used as input to the GEANT4 detector simulation and are embedded in real data. Generated events have the DCAR values smeared and offset according to the parameters obtained for light hadrons as described in Sec. IV A. Simulated events are also weighted according to the momentum distribution of background-subtracted (combinatorial dimuon and FVTX-MuTr mismatch) muons from real data dimuons. Figure 6 shows the DCAR distributions obtained from these prompt \( J/\psi \) and \( B \to J/\psi \) simulations. Several hypotheses of \( B \to J/\psi \) nuclear modifications are considered in the momentum weighting for systematic uncertainty evaluations and described in Sec. VI A 2. Point-to-point statistical fluctuations in the generated DCAR distributions are minimized by using fitted analytical functions for the final DCAR fits. The DCAR distributions obtained from prompt \( J/\psi \) simulation are well described by a three-Gaussian \((G_1, G_2, \text{and } G_3)\) function with a detector offset and resolutions \( \sigma_1, \sigma_2, \text{and } \sigma_3 \), and regulated by \( f_1 + f_2 + f_3 = 1 \):

\[
\frac{\text{det.resp(DCAR)}}{N} = f_1 G_1(\text{DCAR}; \text{offset}, \sigma_1) + f_2 G_2(\text{DCAR}; (dca02 - \text{offset}), \sigma_2) + f_3 G_3(\text{DCAR}; (dca03 - \text{offset}), \sigma_3). \tag{9}
\]

The following function defines the prompt \( J/\psi \) DCAR line shape of prompt \( J/\psi \) decays

\[
\text{decay}_{J/\psi}(\text{DCAR}) = \delta(0) \otimes \text{det.resp(DCAR)}. \tag{10}
\]

The true DCAR distribution for heavy flavor decays is described by a set of three exponential functions:

\[
\text{decay}_{\text{true}}(\text{DCAR}) = \begin{cases} 
\frac{f_d}{1 - f_d} e^{-\text{DCAR} / \sigma_c} & \text{DCAR} < 0 \\
(1 - f_1 - f_2) e^{-\text{DCAR} / \sigma_c} & \text{DCAR} > 0
\end{cases}
\tag{11}
\]
FIG. 9. (a) Simulated correlated background components, in the dimuon mass \( \in [2.9,3.5] \text{ GeV}/c^2 \), after momentum weighting and vertex uncertainty along with fitted function Eq. (12). Boxes represent the bin widths and statistical uncertainties in simulation. (b), (c) Pulls between simulated data points and fitted functions.

which must be convoluted with the detector response function Eq. (9) extracted from the prompt \( J/\psi \) fit to obtain the measured DCAR distribution:

\[
\text{decay}(\text{DCAR}) = \text{decay}^{\text{true}}(\text{DCAR}) \otimes \text{det.resp}(\text{DCAR}).
\]

The dashed line in Fig. 6 shows function Eq. (12) fitted to the simulated \( B \to J/\psi \) decays. Function Eq. (12) is also used to fit the simulated correlated background components \( c\bar{c} \) and \( b\bar{b} \) as seen in Fig. 9. The heavy flavor decay functions used in the final fit are

\[
\text{decay}_D(\text{DCAR}) = \text{decay}(\text{DCAR}; \to \mu)
\]

\[
\text{decay}_B(\text{DCAR}) = \text{decay}(\text{DCAR}; \to \mu)
\]

\[
\text{decay}_{B \to J/\psi}(\text{DCAR}) = \text{decay}(\text{DCAR}; \to \mu)
\]

where \( \text{decay}_{D} \), \( \text{decay}_{B} \), and \( \text{decay}_{B \to J/\psi} \) are the parameters in Eq. (11) fitted to the corresponding heavy flavor decay simulations.

V. FITTING PROCEDURE

The final fitting function used for the real-data muon DCAR distribution is

\[
f_\mu(\text{DCAR}) = \text{BG}_{\text{uncorr}}(\text{DCAR}) + \text{BG}_{\text{corr}}(\text{DCAR})
\]

\[
+ N_{J/\psi}[\left(1 - f_{bb}\right)\text{decay}_D(\text{DCAR})
+ f_{bb}\text{decay}_B(\text{DCAR})],
\]

where \( \text{BG}_{\text{uncorr}} \) includes the normalized dimuon combinatorial (Sec. III A) and FVTX-MuTr mismatch (Sec. III B) backgrounds. The correlated background \( \text{BG}_{\text{corr}} \) comprises \( c\bar{c} \) and \( b\bar{b} \) contributions:

\[
\text{BG}_{\text{corr}}(\text{DCAR}) = N_{\text{corr}} f_{\text{cont}}[1 - f_{bb}]\text{decay}_D(\text{DCAR})
+ f_{bb}\text{decay}_B(\text{DCAR})],
\]

where \( N_{\text{corr}} \) is the number of muons after subtracting \( \text{BG}_{\text{uncorr}} \). The continuum correlated background \( f_{\text{cont}} \) is defined in Table II. The muon count from inclusive \( J/\psi \) decays is

\[
N_{J/\psi} = (1 - f_{\text{cont}})N_{\text{corr}}.
\]

The fraction of \( b\bar{b} \) contribution in

FIG. 10. (a), (b) Function Eq. (14) fitted to the \( p + p \) data in different rapidity ranges. The combinatorial and FVTX-MuTr mismatch backgrounds are subtracted from both data and the fitting function for clarity. The band around the total fit curve corresponds to the propagated fitting uncertainty. The resulting \( F_{B \to J/\psi} \) is corrected by the relative acceptance and efficiency, and the evaluated uncertainty is only from the fit. (c), (d) Pulls between data points and fitted functions.
the correlated background $f_{bb}$ was determined from extrapolations of previous $c\bar{c}$ and $b\bar{b}$ cross section measurements [28,29], indicating a fraction $f_{bb} = 0.32 \pm 0.21$ in $p+p$ collisions at $\sqrt{s} = 200$ GeV. The $b\bar{b}$ contribution in the correlated background is completely undetermined in Cu+Au collisions. So we set $f_{bb} = 0.5$ in the standard fit and vary it in the range $f_{bb} \in [0,1]$ for the systematic uncertainty evaluation.

The measured fraction of $B$-meson decays $F_{\text{meas}}^{B\rightarrow J/\psi}$ is the only free parameter when fitting function Eq. (14) to the real-data muon DCA$_R$ distribution. The true $F_{B\rightarrow J/\psi}$ is obtained by correcting the measured $F_{B\rightarrow J/\psi}$ with a factor given by the relative detector acceptance and efficiency of $J/\psi$ from $B$-meson decays with respect to prompt $J/\psi$ decays,

$$\frac{1}{F_{B\rightarrow J/\psi}} = 1 + \left( \frac{1}{F_{\text{meas}}^{B\rightarrow J/\psi}} - 1 \right) \frac{\varepsilon_B}{\varepsilon_{J/\psi}},$$

where $\varepsilon_B/\varepsilon_{J/\psi} \in [0.96,0.98]$ depending on the data set ($p+p$ or Cu+Au) and muon arm.

The fit is performed with an unbinned extended log-likelihood method, where

$$-\ln L = \sum_{i=1}^{N_{\mu}} - \ln f_{\mu}(\text{DCA}_R;F_{B\rightarrow J/\psi}) - N_{\mu}$$

is minimized. $N_{\mu}$ is the number of muons in the DCA$_R$ distribution, including the backgrounds. Figures 10 and 11 show the fitted function Eq. (14) to the DCA$_R$ distributions in $p+p$ and Cu+Au collisions, respectively. The backgrounds due to combinatorial dimuons and FVTX-MuTr mismatches are subtracted for clarity in the figures. The bars in the figure show the total uncertainties of each data point.

VI. SYSTEMATIC UNCERTAINITIES

The systematic uncertainties are determined by fitting $f_{\mu}(\text{DCA}_R)$ in function Eq. (14) several times, using random variations of the fitting parameters for each fit. This section lists all considered systematic uncertainty sources and how they affect the final results.

A. List of systematic uncertainty sources

1. Testing of the fitting procedure

The validity of the fitting procedure was tested by randomly generating DCA$_R$ distributions for backgrounds, $B\rightarrow J/\psi$, and prompt $J/\psi$, with $F_{B\rightarrow J/\psi}$ tested in the range [0, 0.4]. The total number of entries in the summed DCA$_R$ distributions were generated to match the real data distributions. The

FIG. 12. (a) Momentum distribution of $F_{B\rightarrow J/\psi}$ from PYTHIA8 (open circles) and a set of $p_T$ and rapidity $B$-meson yield modifications relative to prompt $J/\psi$ (closed symbols) defined in panels (b)–(f). Scales on $F_{B\rightarrow J/\psi}$ are arbitrary.
fit results over thousands of randomly generated DCAR distributions in each \( F_{B \rightarrow J/\psi}^{\text{generated}} \) return \( F_{B \rightarrow J/\psi}^{\text{measured}} \) with average bias \(|F_{B \rightarrow J/\psi}^{\text{generated}} - F_{B \rightarrow J/\psi}^{\text{measured}}| < 0.005 \) in Cu+Au data and negligible in \( p + p \) data.

2. Weighting of simulated samples

All detector reconstructed simulated samples were weighted according to the single muon momentum distributions of real data muons from \( J/\psi \) decays used in the DCAR distributions. This weighting already accounts for the realistic momentum distribution of measured dimuons in the \( J/\psi \) mass region. Figure 12 shows how the momentum distribution of muons from \( B \rightarrow J/\psi \) decays are distributed relative to muons from prompt \( J/\psi \) decays in several conservative \( B \)-meson \( p_T \) and rapidity yield modification hypotheses. The inverse momentum dependence obtained from the several hypotheses can be described by polynomials of degree one \( f_{B \rightarrow J/\psi}(p) \). The maximum deviation from the assumption used in the standard result is \(|f_{B \rightarrow J/\psi}(p) - F_{B \rightarrow J/\psi}| < 0.005 \). This value is used in the systematic uncertainty determination.

3. DCAR resolutions and offsets in simulation

A relative variation of 15% in the detector offset, 5% for \( \sigma_{r} \), and 7% for \( \sigma_{y} \) are found when different fitting ranges are used to determine the offset and the momentum dependence of the DCAR detector resolution shown in Figs. 8(c), 8(d), 8(g), and 8(h). Varying these parameters within their uncertainties produces fluctuations on the \( F_{B \rightarrow J/\psi} \) result of up to 0.015.

4. DCAR tail contribution to the detector response function

The detector response function Eq. (9) is fitted to simulated and real data hadrons shown in Fig. 8. The third Gaussian, which accounts for the long range tails in the DCAR distributions, has a contribution which is 20% different between real and simulated data. This difference can be caused by (1) modified light hadron decay in real data, (2) bias in the FVTX-MuTr mismatch distribution normalization (5); or (3) missing accidental hit-track associations in simulation. The third Gaussian contribution in Eq. (9), \( f_3 \), is varied by 20% to account for these uncertainties. This variation produces a change in the \( F_{B \rightarrow J/\psi} \) of up to 0.004.

5. Relative detector acceptance and efficiency

Variations in the PYTHIA8 parameters, such as renormalization factor and additional weighting to match measured \( J/\psi \) rapidity and \( p_T \) distributions in Ref. [30], used to determine the relative detector acceptance and efficiency \( \epsilon_{B/\psi} \) introduce 1% relative fluctuation in the \( F_{B \rightarrow J/\psi} \) result in the \( p + p \). When considering different scenarios for the \( B \)-meson nuclear modification in Cu+Au; including variations with centrality \( p_T \) and rapidity; the fluctuation in \( F_{B \rightarrow J/\psi} \) relative to the default result is 5%.

6. Dimuon combinatorial background and FVTX-MuTr mismatch distribution normalizations

The dimuon combinatorial background normalization Eq. (1) varies by up to 3% when changing the mass range used to determine it. Another concern is how particle activity surrounding a \( B \) meson can affect the normalization Eq. (5) of FVTX-MuTr mismatch distributions. The normalization shows a 5% variation when embedding entire PYTHIA8+GEANT4 events containing prompt \( J/\psi \) and \( B \rightarrow J/\psi \). When applying these variations in the DCAR fitting Eq. (14), the \( F_{B \rightarrow J/\psi} \) result has a standard deviation of 0.01.

7. Correlated background

The dimuon mass fitting uncertainty for the correlated background contributions shown in Table II is introduced as Gaussian random numbers before each fit. The fraction of \( b\bar{b} \) in the correlated background is varied by \( f_{b\bar{b}} = 0.32 \pm 0.21 \) in...
\[ p \pm p \text{ collisions based on the uncertainties in the total } c\bar{c} \text{ and } b\bar{b} \text{ cross section} \text{[28,29]. For } Cu+Au \text{ collisions, } f_{g,6} \in [0, 1] \text{ is considered, which accounts for unknown } c\bar{c} \text{ and } b\bar{b} \text{ nuclear modifications. When applying these variations in the fitting procedure defined in Eq. (14) the } F_{B \to J/\psi} \text{ standard deviation is } 0.01 \text{ in } p + p \text{ and } 0.025 \text{ in } Cu+Au. \]

**B. Total systematic uncertainties**

Table IV summarizes all systematic uncertainty contributions. The total systematic uncertainty also listed in the table is obtained by varying the parameters as described in the fitting function Eq. (14) simultaneously, assuming all variations are independent, and running several independent fits.

**C. Other checks**

Other tests such as variations in the DCA_{R} fitting range, and the use of simulated histograms rather than functions as fitting input, provided results that are statistically consistent with the default result. No additional systematic uncertainties are assigned from these checks.

\[ d\sigma_{b\bar{b}} / dy = \frac{1}{2} d\sigma_{J/\psi} / dy \times F_{B \to J/\psi}, \quad (17) \]

where \( d\sigma_{J/\psi} / dy \) is obtained from \( J/\psi \) measurement by PHENIX [30]. The branching ratios \( Br(B \to J/\psi + X) \) and \( Br(J/\psi \to \mu^{+}\mu^{-}) \) are reported in the particle data group [3]. The factor \( \frac{1}{2} \) accounts for the fact that both b quarks in the \( b\bar{b} \) pair contribute to the \( F_{B \to J/\psi} \). The results are shown in Table VI, where the average rapidity \( \langle y \rangle \) are obtained from the detector acceptance of \( B \to J/\psi \) events generated by PYTHIA8. Table VI also presents the corresponding FONLL calculation.

**C. B-meson nuclear modification**

The nuclear modification factor is defined by

\[ R_{CuAu} = \frac{(dN/dy)_{CuAu}}{(dN/dy)_{pp}}, \quad (18) \]

where \( dN/dy \) is the yield in Cu+Au and \( p + p \) collisions and \( (N_{col}) \) is the average number of binary collisions in the

**VII. RESULTS**

**A. Fraction of B mesons in the \( J/\psi \) sample**

The acceptance and efficiency corrected \( B \)-meson contributions to the \( J/\psi \) yields collected in \( p + p \) and \( Cu+Au \) data are listed in Table V and plotted in Fig. 13. The detector acceptance and efficiency of \( B \)-meson decays producing a \( J/\psi \) in the muon arm apertures is shown in Fig. 14 as a function of rapidity and transverse momentum. The estimation is obtained from the simulation setup described in Sec. IV embedded in \( Cu+Au \) raw data. As can be seen in the right panel, the measurement presented in this analysis is the first which covers \( B \) mesons starting from zero \( p_{T} \) in heavy ion collisions.

The \( F_{B \to J/\psi} \) obtained in \( p + p \) collisions is well described by a theoretical calculation based on FONLL [31,32] for the \( B \to J/\psi \) and color-evaporation-Model (CEM) [33] for the prompt \( J/\psi \) differential cross sections. Uncertainties in the theoretical calculation come from the bottom quark mass (4.5–5.0 GeV/c^2) and scale uncertainties. The CTEQ6 parton-density function [34] was adopted in both FONLL and CEM calculations.

**B. Differential cross section of \( b\bar{b} \) in \( p + p \) collisions**

The corresponding \( p + p \to b\bar{b} \) differential cross section can be calculated by

\[ \frac{d\sigma_{b\bar{b}}}{dy} = \frac{1}{2} \frac{d\sigma_{J/\psi}}{dy} \times F_{B \to J/\psi}, \quad (17) \]

where \( d\sigma_{J/\psi} / dy \) is obtained from \( J/\psi \) measurement by PHENIX [30]. The branching ratios \( Br(B \to J/\psi + X) \) and \( Br(J/\psi \to \mu^{+}\mu^{-}) \) are reported in the particle data group [3]. The factor \( \frac{1}{2} \) accounts for the fact that both b quarks in the \( b\bar{b} \) pair contribute to the \( F_{B \to J/\psi} \). The results are shown in Table VI, where the average rapidity \( \langle y \rangle \) are obtained from the detector acceptance of \( B \to J/\psi \) events generated by PYTHIA8. Table VI also presents the corresponding FONLL calculation.

**C. B-meson nuclear modification**

The nuclear modification factor is defined by

\[ R_{CuAu} = \frac{(dN/dy)_{CuAu}}{(dN/dy)_{pp}}, \quad (18) \]

where \( dN/dy \) is the yield in Cu+Au and \( p + p \) collisions and \( (N_{col}) \) is the average number of binary collisions in the

**FIG. 13. Fraction \( F_{B \to J/\psi} \) of \( B \)-meson decays in the inclusive \( J/\psi \) sample in \( p + p \) and \( Cu+Au \) collisions at \( \sqrt{s_{NN}} = 200 \text{ GeV} \) versus rapidity along with a theoretical estimation based on fixed-order plus next-to-leading logs (FONLL) [31,32] for the \( B \to J/\psi \) cross section and color-evaporation-model (CEM) [33] for the prompt \( J/\psi \). The statistical uncertainties are represented by the error bars and the systematic uncertainties are represented by filled boxes.**

**FIG. 14. Detector acceptance \times efficiency of \( B \)-meson decays producing a \( J/\psi \) in the muon arms (1.2 < \( |y| \) < 2.2) versus \( B \)-meson (a) and rapidity (b) \( p_{T} \). The statistical uncertainties in simulation are shown in filled gray bands.**
Cu+Au data sample. The Glauber estimated average number of collisions in Cu+Au collisions is \( \langle N_{\text{coll}} \rangle = 108 \pm 11 \). The centrality and \( p_T \) integrated \( R_{\text{CuAu}} \) for inclusive \( J/\psi \) in Cu+Au collisions is obtained from the results presented in Ref. [17]: 0.365 ± 0.019(stat) ± 0.026(syst) in the Au-going direction and 0.295 ± 0.026(stat) ± 0.021(syst) in the Cu-going direction with a global uncertainty of 7.1%. The separated prompt \( J/\psi \) and \( B \)-meson \( R_{\text{CuAu}} \) can be extracted from inclusive \( J/\psi \) \( R_{\text{CuAu}} \) and \( F_{B \to J/\psi} \) through

\[
R_{\text{CuAu}}^{\text{prompt}} = \frac{1 - F_{\text{CuAu}}^{B \to J/\psi}}{1 - F_{\text{pp}}^{B \to J/\psi}} R_{\text{CuAu}}^{\text{incl}}, \quad R_{\text{CuAu}}^{B} = \frac{F_{\text{CuAu}}^{B \to J/\psi}}{F_{\text{pp}}^{B \to J/\psi}} R_{\text{CuAu}}^{\text{incl}},
\]

(19)

where \( R_{\text{CuAu}}^{\text{prompt}}, R_{\text{CuAu}}^{B}, \) and \( R_{\text{CuAu}}^{\text{incl}} \) are the nuclear modification factors for prompt \( J/\psi \) \( B \) mesons and inclusive \( J/\psi \) and \( B \) mesons, respectively.

The average of the results for \( F_{B \to J/\psi} \) shown in the first two rows of Table V is used as a \( p + p \) reference \( F_{\text{pp}}^{B \to J/\psi} \). The uncertainties in the DCA\(_R\) resolution in simulation are correlated between the \( p + p \) and Cu+Au analysis and cancel out in the \( R_{\text{CuAu}} \) results. The global uncertainty includes statistical and systematic uncertainties of the \( p + p \) reference. Table VII and Fig. 15 summarizes the \( B \)-meson and prompt-\( J/\psi \) nuclear modifications obtained using Eq. (19).

Both nuclear modifications factors from forward and backward rapidities are consistent with binary scaling of \( p + p \) yields given the large uncertainties. The results are also consistent with initial-state effects predicted by the EPS09 model [12], shown in Fig. 15, which suggests a modest enhancement. The EPS09 calculation uses as input \( x \) and \( Q^2 \) from \( gg \to bb \) events generated by PYTHIA8. The same model underpredicts the large yield enhancements observed for leptons from inclusive heavy flavor, dominated by charm quarks, at midrapidity and negative rapidity in \( d + Au \) collisions [14,15] at the same energy. Heavy flavor yield enhancement at large-\( x \), which dominates the negative rapidity yield, is also expected from incoherent multiple scattering of initial gluons [9].

Binary scaling of momentum-integrated heavy flavor production was previously observed in electron yields from charm quarks by PHENIX [35] and reconstructed \( D \) mesons by STAR [36] in \( Au + Au \) collisions at RHIC. The \( p_T \) integrated \( B \)-meson nuclear modification result obtained in this work, when combined with these earlier results, indicate there is binary scaling of \( B \) and \( D \) mesons separately. Because charm and bottom number are conserved in heavy ion collisions at \( \sqrt{s_{NN}} = 200 \) GeV, the interaction with the QGP medium only alters the momentum distribution of \( D \) mesons and \( B \) mesons causing a relative yield suppression for \( p_T \gg m_Q \).

**VIII. SUMMARY AND CONCLUSIONS**

We report the fraction of \( B \)-meson decays in the inclusive \( J/\psi \) yield in \( p + p \) and \( Cu + Au \) collisions at \( \sqrt{s_{NN}} = 200 \) GeV. The measurement is centrality and \( p_T \) integrated with acceptance starting from zero \( p_T \) \( B \) mesons. The \( bb \) differential cross section obtained from the measured fractions at rapidity \( 1.2 < |y| < 2.2 \) in \( p + p \) collisions is consistent with FOPI nuclear theoretical calculation within uncertainties [31,32]. A systematically larger fraction is observed in \( Cu + Au \) collisions than in \( p + p \) collisions, which reflects a smaller nuclear modification of \( B \) mesons in \( Cu + Au \) collisions compared to prompt \( J/\psi \). The nuclear modification factor calculated from the \( Cu + Au \) and \( p + p \) fractions, along with the measured inclusive \( J/\psi \) \( R_{\text{CuAu}} \), are listed in Table VII and shown in Fig. 15. The results are consistent with binary scaling of \( B \)-meson yields. No significant difference is observed between the Cu-going and Au-going direction within the result uncertainties. However, yield enhancement at negative rapidity is favored, which is in agreement with cold-nuclear-matter effects observed for inclusive heavy flavor in \( d + Au \) collisions at the same energy [14,15], an EPS09-based calculation, and

---

**TABLE VI.** Differential cross section for \( p + p \to bb \) at \( \sqrt{s} = 200 \) GeV obtained from Eq. (17) along with the FONLL theoretical calculation [31,32].

| \( y \)   | \( d\sigma_{bb}/dy \) [\( \mu b \)] |
|----------|-------------------------------------|
| \(-1.6\) | \(0.51 \pm 0.16\) (stat) ± 0.20(syst) |
| \(1.6\)  | \(0.52 \pm 0.21\) (stat) ± 0.21(syst) |
| \(|1.6|\) | \(0.51 \pm 0.13\) (stat) ± 0.20(syst) |
| \(|1.6|\) (FONLL) | \(0.26^{+0.15}_{-0.10}\) (theory uncert.) |

---

**TABLE VII.** Nuclear modification factors of \( B \) mesons and prompt-\( J/\psi \) obtained from Eq. (19).

|          | \( R_{\text{CuAu}}^{B} \) |
|----------|-----------------------------|
| Au-going | \(1.37 \pm 0.41\) (stat) ± 0.33(syst) ± 0.47(pp) |
| Cu+going | \(1.05 \pm 0.31\) (stat) ± 0.28(syst) ± 0.47(pp) |
|          | \( R_{\text{CuAu}}^{\text{prompt}} \) |
| Au-going | \(0.339 \pm 0.021\) (stat) ± 0.026(syst) ± 0.075(pp) |
| Cu+going | \(0.276 \pm 0.026\) (stat) ± 0.023(syst) ± 0.075(pp) |
incoherent multiple scattering of initial gluons. This result and others on charm yields indicate that heavy-quark number is conserved in heavy ion collisions at $\sqrt{s_{NN}} = 200$ GeV. Interaction with the QGP medium only alters momentum distributions of $D$ and $B$ mesons. The nuclear modification observed for $B$ mesons contrasts with the strong suppression measured for prompt $J/\psi$ mesons indicating that final-state effects, where the $cc$ binding is broken by the medium formed, are dominant for prompt $J/\psi$ mesons.

ACKNOWLEDGMENTS

We thank the staff of the Collider-Accelerator and Physics Departments at Brookhaven National Laboratory and the staff of the other PHENIX participating institutions for their vital contributions. We acknowledge support from the Office of Nuclear Physics in the Office of Science of the Department of Energy, the National Science Foundation, Abilene Christian University Research Council, Research Foundation of SUNY, and Dean of the College of Arts and Sciences, Vanderbilt University (USA), Ministry of Education, Culture, Sports, Science, and Technology and the Japan Society for the Promotion of Science (Japan), Conselho Nacional de Desenvolvimento Científico e Tecnológico and Fundação de Amparo à Pesquisa do Estado de São Paulo (Brazil), Natural Science Foundation of China (People’s Republic of China), Croatian Science Foundation and Ministry of Science and Education (Croatia), Ministry of Education, Youth and Sports (Czech Republic), Centre National de la Recherche Scientifique, Commissariat à l’Énergie Atomique, and Institut National de Physique Nucléaire et de Physique des Particules (France), Bundesministerium für Bildung und Forschung, Deutscher Akademischer Austausch Dienst, and Alexander von Humboldt Stiftung (Germany), National Science Fund, OTKA, EÖFP, and the Ch.
