(August 6, 1996)

Previously we have presented evidence for stripe order of holes and spins in La$_{1.6-x}$Nd$_{0.4}$Sr$_x$CuO$_4$ with $x = 0.12$. Here we show, via neutron diffraction measurements of magnetic scattering, that similar order occurs in crystals with $x = 0.15$ and 0.20. Zero-field-cooled magnetization measurements show that all 3 compositions are also superconducting, with the superconducting transition temperature increasing as the low-temperature staggered magnetization decreases.

74.72.Dn, 71.45.Lr, 75.50.Ee, 75.70.Kw

Neutron scattering studies of dynamical magnetic correlations in superconducting La$_{2-x}$Sr$_x$CuO$_4$ have provided important clues to the nature of electronic correlations within the doped CuO$_2$ planes. The low-energy magnetic scattering, which is characterized by the two-dimensional antiferromagnetic wavevector $Q_{AF} = (\frac{1}{2}, \frac{1}{2})$ (measured in units $2\pi/a$) at low doping, shifts to positions $(\frac{1}{2} \pm \epsilon, \frac{1}{2})$ and $(\frac{1}{2}, \frac{1}{2} \pm \epsilon)$, with $\epsilon \approx x$ for $x > 0.05$. In one common interpretation, the incommensurate peaks are viewed as the dynamical response of a spatially uniform electron liquid with a nearly-fermi Fermi surface. From a rather different perspective, the $Q$-dependent structure is taken as evidence for spatial inhomogeneity associated with charge segregation or charge-density-wave correlations. Evidence for the latter picture is provided by our recent discovery of incommensurate charge and spin order in La$_{1.6-x}$Nd$_{0.4}$Sr$_x$CuO$_4$ with $x = 0.12$; however, given the claim that bulk superconductivity is absent at this composition, one might choose to argue that these results are not directly relevant to the case of superconducting samples.

To test the relationship between charge-stripe order and superconductivity, we have now investigated two other Sr concentrations, $x = 0.15$ and 0.20. Our neutron diffraction measurements on single-crystal samples reveal elastic incommensurate magnetic peaks for both compositions, thus demonstrating the presence of charge-stripe order. Since the $x = 0.20$ crystal was known to be superconducting from previous work, we decided to check the $x = 0.12$ and 0.15 crystals for superconductivity as well. To our surprise, zero-field-cooled susceptibility measurements exhibit a bulk shielding signal for all three compositions. Since both the incommensurate peak splitting, $\epsilon$, and the superconducting transition temperature vary with $x$, the results strongly suggest a local coexistence of superconductivity and stripe order. The fact that $T_c$ decreases as the staggered magnetization increases indicates that these two types of order compete with one another. Furthermore, since the variation of $\epsilon$ with $x$ in the Nd-doped crystals is essentially identical to that obtained from recent inelastic measurements on crystals of La$_{2-x}$Sr$_x$CuO$_4$, it seems inescapable that dynamical charge-stripe correlations are present in the optimally doped material.

The crystals studied in this work were grown at the University of Tokyo using the traveling-solvent floating-zone method. The transport properties of the $x = 0.12$ and 0.20 compositions were reported several years ago; the $x = 0.15$ and further $x = 0.12$ crystals were grown more recently. The neutron diffraction measurements on the $x = 0.15$ and 0.20 crystals were performed on triple-axis spectrometers at the High-Flux Beam Reactor, Brookhaven National Laboratory, utilizing cryostats and spectrometer conditions similar to those used in the previous work on $x = 0.12$, which is described in detail elsewhere.

Scans through the magnetic peaks at $Q = (\frac{1}{2} \pm \epsilon, \frac{1}{2}, 0)$ are shown in Fig. 1. Sharp elastic peaks (with resolution-limited widths in these coarse-resolution scans) are found for all three Sr concentrations. The peak splitting parameter, $\epsilon$, is distinctly different in each sample, and clearly increases with $x$. The temperature dependences of the magnetic peak intensities (normalized to sample volume) are presented in Fig. 2. Both the ordering temperature and the relative intensity (proportional to the square of the staggered magnetization) decrease with $x$. The sharp upturn in intensity at low $T$ that is apparent for the $x = 0.20$ sample is identical to that found previously for $x = 0.12$, and is due to ordering of the Nd moments via coupling to the Cu ions. The Nd ordering provides a useful amplification of the Cu order.

Unfortunately, there is no such incidental amplification of the charge-order peaks, which were already quite weak for $x = 0.12$. An extremely weak signal was detected at the expected position $(2 + 2\epsilon, 0, 0)$ for the $x = 0.15$ crystal at 10 K, but it was not practical to determine its temperature dependence. No search for a charge-order
peak in the $x = 0.20$ sample was even attempted due to the small size of the crystal ($\sim 0.05 \text{ cm}^3$) and to the weakness of the magnetic signal. Nevertheless, even without a direct observation of charge order (or, rather, the corresponding lattice modulation to which neutrons are sensitive), a modulation of the charge density is implied by the incommensurate magnetic order. The argument behind this assertion is as follows. The magnetic incommensurability indicates there there exists a modulation of either the spin orientations (spiral order) or the spin density [24]; a combination of these two is also possible. We have argued elsewhere [20] that the secondary ordering of the Nd moments is incompatible with perfect spiral order of the Cu spins within a plane; therefore, there must be a spin-density-wave component to the order. Symmetry allows a spin modulation with wave vector $q$ to couple to a charge modulation at $2q$. It follows that a charge-density modulation must be present; the only real issues concern the magnitude of the modulation and the driving mechanism. In the case of $x = 0.12$, the neutron diffraction data indicate that the order is driven by the charge [14,20,24]. There is nothing to suggest that the physics is any different in the $x = 0.15$ and 0.20 crystals.

To test for superconductivity in the crystals (or pieces thereof), the bulk magnetic susceptibility was measured with a SQUID (superconducting quantum-interference device) magnetometer, using a magnetic field in the range of 1–5 G. Attempts to measure the Meissner effect (by cooling in a magnetic field) yielded a weak paramagnetic upturn at $T_c$. On the other hand, measurements performed after cooling in zero field (see Fig. 3) give a shielding signal $> 100\%$ (without correction for demagnetization). Meissner-effect measurements on large samples are notoriously difficult due to flux-pinning effects, whereas shielding measurements tend to be less problematic [24]. We believe that the shielding results provide reliable evidence of bulk superconductivity in the crystals. The variation of $T_c$ with $x$ argues against associating the superconductivity with an impurity phase.

There have been disagreements in the literature [26,21] concerning the existence of bulk superconductivity in La$_{1.6-x}$Nd$_{0.4}$Sr$_x$CuO$_4$ for $x \lesssim 0.2$. In particular, Büchner et al. [21] have argued against bulk superconductivity on the basis of Meissner-effect and specific-heat measurements. We have already mentioned the difficulties with Meissner measurements. For the specific heat, it is observed in the cuprates that the jump at $T_c$ rapidly becomes smeared as doping conditions deviate from optimal [27]; hence, it is not surprising if a superconducting transition is not readily apparent in specific-heat measurements on a sample with a severely depressed $T_c$. As a check on the present single-crystal results, a series of ceramic samples was prepared. Shielding measurements confirm the existence of bulk superconductivity, except at $x = 0.07, 0.115, \text{ and } 0.12$. The variation of $T_c$ with $x$ is compared with the single-crystal results in Fig. 4(c).

The behaviors are reasonably consistent. The values of $T_c$ for single crystals of La$_{2-x}$Sr$_x$CuO$_4$ studied recently by Yamada et al. [8] are also included (open circles).

The reduction of $T_c$ induced by the Nd substitution is correlated with a modification of the low-temperature tilt pattern of the CuO$_6$ octahedra [20]. The Nd causes a change in the tilt direction from [110], as in the low-temperature-orthorhombic (LTO) phase, to [100], characteristic of the low-temperature-tetragonal (LTT) phase, with the transition occurring at a temperature of roughly 70 K. A coupling between the tilt modulation and the charge-stripe correlations is possible only when the tilts have a [100] orientation, parallel to the charge modulation. One might expect that the degree to which the charge modulations can be pinned would depend on the amplitude of octahedral tilts. Büchner et al. [21] have shown that a useful measure of the tilt amplitude (or actually its square) is the maximum difference between $a$ and $b$ lattice parameters in the LTO phase. The values of $b - a$ measured by neutron diffraction on our Nd-doped crystals are shown as a function of Sr concentration in Fig. 4(a); for comparison, the square of the staggered magnetization (low-temperature magnetic peak intensity normalized relative to the $x = 0.12$ result) is presented in (b). The strength of the magnetic order is clearly correlated with the size of the tilt modulation, consistent with the pinning argument. The magnitude of $T_c$ reduction is also correlated with the tilt modulation. Superconductivity and stripe order compete with each other, but also coexist.

Of course, the hole concentration also varies with $x$, and this is reflected in the variation of the magnetic-peak-splitting parameter, $\epsilon$, as indicated by the filled circles in Fig. 4(d). The open circles are the results of inelastic measurements on crystals of La$_{2-x}$Sr$_x$CuO$_4$ by Yamada et al. [7]. The trends with $x$ are essentially identical, implying that the nature of the instantaneous correlations in the two systems is the same. The recent observation [6] that high-energy spin fluctuations in La$_{1.86}$Sr$_{0.14}$CuO$_4$ behave like damped spin waves certainly seems consistent with the presence of stripe correlations. The only significant difference between the crystals with and without Nd appears to be the degree of pinning of the stripe correlations. Fluctuations of the stripe correlations seem to be important for achieving a high $T_c$.

Theoretically, calculations by Viertiö and Rice [28] indicate that charged domain walls in a doped antiferromagnet will tend to melt due to quantum fluctuations. This result is quite consistent with experiment: no static stripe order is observed in optimally-doped La$_{2-x}$Sr$_x$CuO$_4$. Quantum melting is inhibited only when a sufficiently strong perturbation, such as that caused by Nd substitution, is applied. The tendency of domain walls to fluctuate has also been considered in other recent studies [29,30]. Fluctuating stripe correlations seem a likely explanation for the quantum critical behavior.
found in La$_{1.86}$Sr$_{0.14}$CuO$_4$ by Aeppli et al. [3].

The spatial modulation of spin and charge densities indicated by our results could be driven either by a Fermi-surface-induced charge-density-wave (CDW) instability or by frustrated phase separation. CDW order is generally stabilized by the opening of a gap about the Fermi energy. Such a gap would seem to be inconsistent with the low resistivity [2] and superconductivity in these samples; furthermore, optical measurements show no evidence for a gap in charge excitations down to 4 meV [3]. On the other hand, in the frustrated-phase-separation model [18], the chemical potential should lie within a band of mid-gap states, consistent with metallic behavior. (An alternative strong-correlation model with charge stripes is described in [33].)

To summarize, we have presented evidence that superconductivity and charge-stripe order coexist in La$_{1.6-x}$Nd$_{0.4}$Sr$_2$CuO$_4$, although the order parameters compete with one another. For a given $x$, the spatial modulation of the spin correlations is the same as in La$_{2-x}$Sr$_x$CuO$_4$ [3], which indicates that the instantaneous correlations are essentially the same in the two systems. There appears to be an intimate connection between stripe correlations and superconductivity in these materials. It will be interesting to test the generality of these results in other families of cuprate superconductors.
