We suggest that to understand the properties of the above and similar systems, it is important to take into account antisymmetric, Dzyaloshinsky-Moriya (DM) spin-spin interactions, which are expected to be present in a tetrahedron on symmetry grounds. Our main result, which is quite general and model dependent only in the details, is that under certain conditions the low-energy singlet dynamics can coexist with weak antiferromagnetism, induced by the DM interactions. It is well known that weak magnetic moments can appear near a magnetic-paramagnetic transition boundary, or in dimer (gapped) systems in the presence of both DM interactions and external magnetic field. In the present work we describe a novel mechanism for weak antiferromagnetic order, which is induced by the DM interactions even without external fields. We show below that such an exotic possibility exists in tetrahedral systems due to the degeneracy of the ground state on a single tetrahedron. The typical excitation signatures are different from those of conventional spin waves and various nontrivial effects in an external magnetic field, such as magnetic field induced order, are also present.

We start with the following spin-1/2 Hamiltonian, which involves both Heisenberg and antisymmetric exchanges:

$$\hat{H} = \sum_{ij} J_{ij} \mathbf{S}_i \cdot \mathbf{S}_j + \sum_{ij} D_{ij} (\mathbf{S}_i \times \mathbf{S}_j),$$

(1)

where the couplings $J_{ij}$ are distributed as shown in Fig. 1(b). The tetrahedra are represented as plaquettes Fig. 1: (a) A tetrahedron with DM vectors represented by arrows (three of the six shown). (b) Two-dimensional lattice of coupled tetrahedra.

in Fig. 1(a), and are assumed to be coupled weakly, i.e. $0 \leq j_1, j_2 \ll J$, where $J$ is the exchange inside one tetrahedron. All couplings are antiferromagnetic. We analyze the model in two dimensions but the inclusion of three-dimensional couplings is straightforward and does not affect our main results. For simplicity of analysis...
and notation we set for now $j_2 = 0$, and the effect of $j_2$ on our results will be discussed later. The DM couplings have relativistic origin and are expected to be weak, usually at most several percent of the Heisenberg exchange, $|\mathbf{D}_{i,j}| \ll J$. The distribution of the couplings $\mathbf{D}_{i,j}$ is very lattice-specific, as the presence of the DM interaction on a particular bond is determined by the symmetry of the environment. We will make the assumption that the $\mathbf{D}_{i,j}$’s are present only on the tetrahedra (where the Heisenberg exchange is also dominant), and are nonzero on every bond within one tetrahedron. The distribution of the six vectors $\mathbf{D}_{i,j}$, written with respect to the principal axes of the cube in Fig.1(a), and consistent with the tetrahedral group is: $\mathbf{D}_{i,j} = \frac{D}{\sqrt{2}} (-1, 1, 0)$, $\mathbf{D}_{24} = \frac{D}{\sqrt{2}} (0, 1, 1)$, $\mathbf{D}_{12} = \frac{D}{\sqrt{2}} (0, 1, -1)$, $\mathbf{D}_{14} = \frac{D}{\sqrt{2}} (1, 0, 1)$, $\mathbf{D}_{23} = \frac{D}{\sqrt{2}} (1, 0, -1)$. Here $D$ is the magnitude of the DM vectors.

The rest of the paper is organized as follows. In Section II we derive the effective Hamiltonian in the weak-coupling limit. The quantum phases of the model are then analyzed in Sections III and IV. Section V contains our conclusions.

II. EFFECTIVE HAMILTONIAN IN THE PRESENCE OF DM INTERACTIONS

First, we describe the states of one tetrahedron, Fig.1(a). For $D = 0$ the ground state is twofold degenerate (with energy $E_0 = -3J/2$) and is in the singlet sector $S^{tot} = 0$. The two ground states are: $|s_1\rangle = \frac{1}{\sqrt{6}} \{[1,2][3,4] + [2,3][4,1]\}$, $|s_2\rangle = \{[1,2][3,4] - [2,3][4,1]\}$, where $[k,l]$ denotes a singlet formed by the nearest-neighbor spins $k$ and $l$. The DM interactions break the continuous spin rotational invariance, leading to an admixture of triplets to the ground state. Introducing the three excited (energy $E_1 = -J/2$) $S = 1$ triplet states $p_x, q_y, t_z$, $\mu = x, y, z$, in the notation of Ref. 11 we obtain the two new ground states, in the limit $D/J \ll 1$:

$$|\Phi\rangle = |s_1\rangle + \frac{3iD}{\sqrt{6}J} ([p_x] | -p_y\rangle + [q_x] | +q_y\rangle)$$ \hspace{1cm} (2)
$$|\Psi\rangle = |s_2\rangle + \frac{iD}{\sqrt{2}J} ([p_x] | +p_y\rangle + [q_x] | -q_y\rangle) + \frac{D}{J} t_z$$ \hspace{1cm} (2)

These states remain degenerate with $E_D^{DM} = -3J/2 - 3D^2/(2J)$, and their wave-functions transform according to the $e_6$ irreducible representation of the tetrahedral point group. The diagonal matrix elements of on-site spins between the modified ground states are zero, whereas the off-diagonal matrix elements acquire finite imaginary values $\langle \Psi| S_{a,n}\rangle \langle \Phi\rangle = \pm iD/\sqrt{6}J$.

The low-energy sector of the Hilbert space has dimensionality $2N_{tot}$, where $N_{tot}$ is the number of spin tetrahedra. The remaining degeneracy is lifted by the inter-tetrahedral couplings, and we proceed to analyze the nature of the new ground state. For this purpose we introduce a pseudo-spin $T = 1/2$ representation, so that $T_z = 1/2$ corresponds to $|\Phi\rangle$ and $T_z = -1/2$ corresponds to $|\Psi\rangle$. We then obtain the effective Hamiltonian in the ground state subspace:

$$\hat{H}_{eff} = -\sum_{\langle i,j\rangle} \left[ \Omega_x T_{x,i} T_{x,j} + \Omega_y T_{y,i} T_{y,j} + \Omega_z T_{z,i} T_{z,j} + \Omega_{x,y} T_{x,i} T_{y,j} + \Omega_{x,z} T_{x,i} T_{z,j} + \Omega_{y,z} T_{y,i} T_{z,j} \right] + \frac{1}{2} \sum_i T_{z,i} \hspace{1cm} (3)$$

Now the site indexes $i,j$ refer to the positions of the tetrahedra, and the summation is over nearest neighbors on a square lattice. To lowest order in $j_1, D$ the couplings in the different pseudospin directions are explicitly:

$$\Omega_x = \frac{j_1^2}{4J}, \quad \Omega_y = j_1 \frac{4D^2}{3J^2}, \quad \Omega_z = \frac{\Omega_x}{3}, \quad h = \frac{2}{3} \Omega_x \hspace{1cm} (4)$$

The mixed coupling depends on the bond direction $\Omega_{x,y,z}^{i,j} = \Omega_x e^{iQ \cdot (i-j)/\sqrt{3}}$, $Q = (\pi, 0)$.

![FIG. 2: Phase diagram of the pseudospin Hamiltonian at zero temperature.](image)

The effective Hamiltonian describes an anistropic ferromagnet in an effective magnetic field $h$ applied along the “hard” $z$-axis. If the field $h$ does not exceed a critical value $h_c$ (which we find to be the physical case, corresponding to $||$), the system breaks the Ising symmetry along the soft $x$ or $y$ axes. The selected direction in the $xy$-plane depends on $\Omega_x/\Omega_y$. The first-order transition line $\Omega_x = \Omega_y$, on mean-field level, separates regions with $\langle T_{x,i} \rangle \neq 0$, $\langle T_{y,i} \rangle = 0$ (for $\Omega_x > \Omega_y$), and $\langle T_{y,i} \rangle \neq 0$, $\langle T_{x,i} \rangle = 0$ (for $\Omega_y > \Omega_x$). The two regions are shown in Fig. 2 as a function of the microscopic parameters. Since $h \neq 0$, throughout the phase diagram $\langle T_{x,i} \rangle \neq 0$. We now discuss in more detail the nature of symmetry breaking in the two phases.

III. DIMER PHASE AND MAGNETIC FIELD INDUCED ORDER

The phase with $\langle T_{x,i} \rangle \neq 0$ corresponds to dimer order. The existence of such a phase for the case $D = 0$
was pointed out in Ref. [1]. Physically, this means that the
ground state of the system is the linear combination
\(\sum_{n} \sqrt{\frac{2}{3}} |\Phi_{n}\rangle \pm \frac{1}{2} |\Psi_{n}\rangle\),
on every site, which is equivalent to
\(\langle T_{x,i} \rangle = \pm \sqrt{3}/4, \langle T_{x,i} \rangle = 1/4\) (these values correspond
to the ground state which is a complex linear combination on
\(\sqrt{3}|\Phi\rangle \pm \frac{1}{2}|\Psi\rangle\), and therefore the expectation values of local spins vanish, and only dimer order is present in this case, as
shown in Fig. 3(a). Since the \(\Omega_{z}\) coupling in [3] has ferromagnetic sign, the dimer pattern repeats itself on all tetrahedra. Magneto-elastic couplings could also contribute to the dimerization tendency as discussed for the pyrochlore case,[12] but in our scenario dimerization occurs spontaneously and is due to purely Heisenberg exchanges.

The dimer ordered state breaks the discrete, Ising symmetry \(T_{x,i} \rightarrow -T_{x,i}\) of the ground state which is a complex linear combination of \(|\Phi\rangle \pm \frac{1}{2}|\Psi\rangle\), and therefore the expectation values of local spins vanish, and only dimer order is present in this case, as shown in Fig. 3(a). Since the \(\Omega_{z}\) coupling in [3] has ferromagnetic sign, the dimer pattern repeats itself on all tetrahedra. Magneto-elastic couplings could also contribute to the dimerization tendency as discussed for the pyrochlore case,[12] but in our scenario dimerization occurs spontaneously and is due to purely Heisenberg exchanges.

\[
\langle T_{x,i} \rangle = \pm \sqrt{3}/4, \langle T_{x,i} \rangle = 1/4 \quad \text{(these values correspond to the ground state which is a complex linear combination on \(\sqrt{3}|\Phi\rangle \pm \frac{1}{2}|\Psi\rangle\), and therefore the expectation values of local spins vanish, and only dimer order is present in this case, as shown in Fig. 3(a). Since the \(\Omega_{z}\) coupling in [3] has ferromagnetic sign, the dimer pattern repeats itself on all tetrahedra. Magneto-elastic couplings could also contribute to the dimerization tendency as discussed for the pyrochlore case,[12] but in our scenario dimerization occurs spontaneously and is due to purely Heisenberg exchanges.}
\]

Due to the presence of triplets in the ground state, a (real) external uniform magnetic field \(-g\mu_{B}H\hat{S}^{\text{tot}}\) also leads to non-trivial effects. On a single tetrahedron \((j_1 = 0)\) the field produces a finite magnetization in the field direction, shown in the inset of Fig. 4. For small fields \(H/J \ll 1\), the contribution is linear and proportional to:
\[
(D/J)^2(H/J).
\]

We find that the magnetization is only weakly dependent on the field direction. For \(j_1 \neq 0\), the corrections to the effective Hamiltonian [3] have to be derived, and we find them to be strongly dependent on the field direction. For example for a weak field in the x-y direction \(H = \frac{H}{\sqrt{2}}(1, 1, 0)\), Eq. (2) changes to:

\[
|\Phi\rangle_{H} = |\Phi\rangle - \frac{\sqrt{3}DH}{2J^2} |p_z\rangle
\]

\[
|\Psi\rangle_{H} = |\Psi\rangle - \frac{\sqrt{3}DH}{2J^2} |q_z\rangle + \sqrt{2}(|t_y\rangle - |t_x\rangle).
\]

The energy difference between these states leads to a modification of the "effective field" \(h \rightarrow h - D^2H^2/(2J^3)\) in Eq. (3). Even though several additional terms are generated in \(\mathcal{H}_{\text{eff}}\), for \(j_1, D, H \ll J\) the above effect is domi-

\[
\Delta(H)/\Delta = \begin{cases}
T_c(H)/T_c & \text{single tetrahedron} \\
D/J=0.3 & \text{dimer phase (B)}
\end{cases}
\]

\[
\text{magnetic phase (B)}
\]

FIG. 4: Dependence of the gap (dashed lines) and \(T_c\) (solid lines) on magnetic field (applied as in Fig. 3(b)) at the points A and B of Fig. 2. Two upper curves shifted by 0.05 for clarity. Inset: Magnetic moment \(\langle S_z^{\text{tot}} \rangle\) in magnetic field in the z direction for a single tetrahedron (results identical in x,y directions). For \(D = 0\), \(\langle S_z^{\text{tot}} \rangle = 0, H_z/J < 1\).

niant. We have recalculated the gap \(\Delta(H)\) and the critical temperature \(T_c(H)\) in the presence of the field and the results are summarized in Fig. 4, where we have plotted these quantities relative to their zero field values. The gap generally shows a stronger field dependence. We note that the increase as a function of field is not universal, and in fact if a field is applied in the z direction \(H = (0, 0, H)\), then \(\Delta(H)\) and \(T_c(H)\) would decrease at almost the same rate.

An applied magnetic field also generates staggered antiferromagnetic moments in the plane perpendicular to the field. The corresponding pattern is shown in Fig. 3(b), where \(\langle S_{z,i} \rangle = \langle S_1 \rangle, \langle S_4 \rangle = \langle S_2 \rangle\), and the spins on sites 2 and 4 point along the diagonals of the cube (towards and out of the cube’s center, respectively). The value of the magnetic moments in this pattern, repeated on all tetrahedra, is

\[
|\langle S_n \rangle| = \frac{DH}{J^2} (T_{x,i}) = \frac{\sqrt{3}DH}{4J^2}, \quad n = 1, 2, 3, 4.
\]

Field induced antiferromagnetic ordering is a general feature of singlet systems with DM interactions.

\[
\begin{align*}
\text{IV. BROKEN TIME-REVERSAL SYMMETRY} \\
\text{STATE WITH WEAK ANTIFERROMAGNETIC ORDER}
\end{align*}
\]

The phase with \(\langle T_{x,i} \rangle \neq 0\) in Fig. 2 corresponds to a ground state which is a complex linear combination on a single tetrahedron \(\alpha|\Phi\rangle \pm i\beta|\Psi\rangle\), where \(\alpha, \beta\) are real coefficients. This combination is ferromagnetically repeated on every tetrahedron. Depending on the values of the microscopic parameters, \(\sqrt{3}/4 \leq |\langle T_{x,i} \rangle| \leq 1/2\).
The resulting state resembles to a large extent a spin-liquid state with a broken time-reversal symmetry proposed some time ago and characterized by finite scalar chirality \( \chi = (S_1 \cdot (S_2 \times S_3)) \neq 0 \). In our case such a state appears, however, due to the anisotropic DM interaction in a system without spin-rotational invariance, and we have \( \chi \sim \langle T_{y1} \rangle \). Therefore, a broken time-reversal symmetry immediately induces finite antiferromagnetic moments with magnitude:

\[
|\langle S_n \rangle| = \frac{D}{T} \sqrt{2} \langle T_{y1} \rangle.
\]

The spins are at an angle \( \phi = 109.47^\circ \) with respects to each other, and form a four-sublattice antiferromagnetic structure, as shown in Fig. 3(c). On each tetrahedron the total magnetic moment \( \sum_n \langle S_n \rangle = 0 \).

Similarly to the dimer phase, the broken Ising symmetry leads to an excitation gap and a finite Ising transition temperature, whose values, for dominant DM interactions are respectively \( \Delta \sim \Omega_y \) and \( T_c \sim \Omega_y \). Thus, we find a quite unusual situation: the specific heat exhibits a large anomaly at the transition temperature, where a macroscopic part of the low-temperature entropy \( N_{\text{int}} \ln 2 \) freezes out. However, if looked at in neutron experiments such a transition is characterized by development of small antiferromagnetic moments below \( T_c \). This exotic behavior is due to the fact that the transition itself is driven by low-energy singlet degrees of freedom. In applied magnetic field \( H = \frac{D}{T} (1, 1, 0) \), the gap and \( T_c \) in the broken time-reversal symmetry state scale as shown in Fig. 4, upper set of curves. We find that generally the field dependence is stronger than in the dimer phase, which is mainly due to the presence of the DM scale \( D \) in the two observables without a field.

We note that \( \Omega_y \) depends linearly on \( j_1 \) while \( \Omega_x \) is quadratic \( 3 \). Thus, even though the \( T_y \) (magnetic) and the \( T_x \) (dimer) orders compete with each other, at sufficiently small \( j_1 \) the \( T_y \) order is expected to dominate (although only in asymptotic sense for the present model). The tendency towards \( T_y \) order is further enhanced by the presence of \( j_2 \neq 0 \) (see Fig. 1(b)). This coupling frustrates the \( T_x \) component while strengthening \( T_y \), which results in a shift of the phase boundary in Fig. 2 downwards. If we also consider a situation when \( j_2 \) is the dominant inter-tetrahedral exchange, \( J \gg j_2 \gg j_1 \), and set \( j_1 = 0 \), then we find that \( T_x \) couplings are generated only in fourth order, \( \Omega_x \sim j_2^3 / J^3 \). This again means that the \( T_y \) order can occur under much easier conditions. Nonetheless, only on lattices that have the tendency to produce true spin liquid ground states do we expect the \( T_y \) order to occur spontaneously. Good candidates appear to be the pyrochlore lattice as well as the kagomé lattice. DM induced ordering has been discussed in the latter case from quasiclassical perspective \( 25 \).

\[ \text{V. DISCUSSION AND CONCLUSIONS} \]

Our calculations have been performed for ideal tetrahedra while weak distortions (such as asymmetry in the Heisenberg exchanges, or deviations of the DM vectors from the tetrahedral symmetry) would introduce a small gap on a single tetrahedron. However, as long as \( j_1, j_2 \) are sufficiently large, relative to this gap, the basic characteristics of the phases described above will remain unchanged. The DM order may deviate from Fig. 3(c), while preserving the property \( \sum_n \langle S_n \rangle = 0 \).

The physics described in the present work occurs on the small energy scales \( \Omega_x, \Omega_y \ll J \), while upon increasing the inter-tetrahedral couplings to \( j_1, j_2 \sim J \), a transition to a more conventional Néel phase is expected to take place \( 5,16 \). The exotic phases we have found are certainly stable as long as the system is sufficiently far from the Néel order, i.e. the triplet gap is non-zero and all the relevant dynamics is governed by the singlet sector (or the mixed states Eq. (2) in the presence of DM interactions), and therefore can be described by the effective Hamiltonian Eq. (3). We have made sure that this condition is fulfilled by using the weak-coupling analysis, although our results are expected to be qualitatively valid also for moderately large \( j_1, j_2 \) subject, as already mentioned, to the condition that the triplet gap is sizable enough. Thus, on general grounds we expect a transition as a function of \( j_1 \) or \( j_2 \) between phases with exotic (weak magnetic) order, discussed in this work, and the Néel ordered state, although the exact determination of the transition boundary is a difficult problem and has not been the subject of this work. Instead, we have concentrated on the “universal” properties of the DM induced exotic phases which are clearly present in the weak-coupling limit and accurately described by a Hamiltonian of the form Eq. (3).

The states we have found at low energies have quite unusual characteristics, which we will now summarize. (i) Due to the presence of the DM interactions the spin-rotational invariance is broken and the ground state develops a small magnetic moment in a field, with the uniform magnetization showing a characteristic linear behavior in weak magnetic fields (Fig. 4(inset)). (ii) Either dimerized or 4-sublattice, weakly antiferromagnetic states emerge as the ground state of the system. Both exhibit gaps in the spectrum since only Ising symmetries are broken. (iii) The dominant components in the wave functions Eq. (2) are singlets, thus a large spectral weight \( S=0 \) transitions at low energy (equal to the gap \( \sim \Omega_x, \Omega_y \)) are present in the Raman spectrum. (iv) Both the gap and \( T_c \) depend on magnetic field with a strong directional dependence. (v) The dominant \( S=1 \) excitation has a large gap of order \( J \gg \Omega_x, \Omega_y \).

We now comment on possible applications of our theory to Cu_2Te_2O_5Br_2. The properties of this material are indeed consistent with signatures (i-iv) above, in particular the compound exhibits \( 4,5 \) (a.) a weak magnetization in a field, (b.) a sharp zero-field, low-energy Raman peak
("singlet gap" $\Delta \approx 24K$), disappearing at $T_c \approx 11K$,
(c.) a magnetic field dependence (increase) of both $\Delta$ and $T_c$. Experimentally the most important unanswered question remains whether the ground state below $T_c$ is magnetically ordered or not, with recent NMR experiments pointing to some kind of magnetic order. This would suggest, in our scenario, that the ground state is of the type shown in Fig. 3(c). The crucial test for our ideas, and thus our prediction, would be the observation of a large triplet gap (larger than the "singlet gap" of 24K) in the neutron spectrum (point (v) above). The microscopic values of the exchanges are still rather controversial and consequently we have not attempted detailed fits but have used, phenomenologically, the model of Fig. 1. We emphasize that in our model a weak magnetic moment is a generic feature of the $\langle T_y, i \rangle \neq 0$ phase (and the dimer phase in magnetic field), and does not require a fine-tuning of parameters to achieve proximity to a magnetic-paramagnetic boundary, as in the purely Heisenberg case.

Finally, on purely fundamental level, we have found an unconventional mechanism for weak antiferromagnetism. Our results are to be contrasted with the usual effect the DM interaction produces, namely weak ferromagnetism in an otherwise antiferromagnetic system. In the present work we have shown how weak antiferromagnetic order can emerge from a singlet background.
