ABSTRACT

Aims. To investigate the universality hypothesis of the initial mass function in the substellar regime, the population of the \( \rho \) Ophiuchi molecular cloud is analysed by including a new sample of low-mass spectroscopically confirmed members. To that end, we have conducted a large spectroscopic follow-up of young substellar candidates uncovered in our previous photometric survey.

Methods. The spectral types and extinction were derived for a newly found population of substellar objects, and its masses estimated by comparison to evolutionary models. A thoroughly literature search was conducted to provide an up-to-date census of the cluster, which was then used to derive the luminosity and mass functions, as well as the ratio of brown dwarfs to stars in the cluster. These results were then compared to other young clusters.

Results. It is shown that the study of the substellar population of the \( \rho \) Ophiuchi molecular cloud is hampered only by the high extinction in the cluster ruling out an apparent paucity of brown dwarfs. The discovery of 16 new members of \( \rho \) Ophiuchi, 13 of them in the substellar regime, reveals the low-mass end of its population and shows the success of our photometric candidate selection with the WIRCam survey. The study of the brown dwarf population of the cluster reveals a high disk fraction of 76\( ^{+5}_{-8} \)%.

Conclusions. Taking the characteristic peak mass of the derived mass function and the ratio of brown dwarfs to stars into account, we conclude that the mass function of \( \rho \) Ophiuchi is similar to other nearby young clusters.

Key words. stars: formation – stars: low-mass, brown-dwarf – stars: planetary system

1. Introduction

Although there is a generally accepted theory of how a star forms through the collapse of a molecular cloud core and contracts to the main sequence (e.g., Shu et al. 1987), two major breakthroughs in the mid-90s have added a new complexity to the star formation field: the discovery of exoplanets (Mayor & Queloz 1995) and brown dwarfs (Oppenheimer et al. 1995, Rebolo et al. 1995, Nakajima et al. 1995). Brown dwarfs are a key element in understanding the origin of stellar masses and their distribution, the initial mass function (IMF), and in identifying the plethora of hospitable hosts where planetary systems can form. However, there is no current consensus regarding their formation mechanism and several scenarios are currently proposed. Some defend a star-like formation, i.e. fragmentation of molecular clouds into low-mass cores driven by turbulence (Padoan & Nordlund 2002, Hennebelle & Chabrier 2008) or gravity (Bonnell et al. 2008). But distinct formation processes are also likely to take place, such as gravitational instabilities in disks (Stamatellos & Whitworth 2009), premature ejection from prestellar cores (Reipurth & Clarke 2001), or photo-erosion of cores (Kroupa & Bouvier 2003). The observational properties of brown dwarfs in young clusters show a global scaling-down trend from those of stars, arguing in favour of a common formation scenario (e.g., Luhan et al. 2007). However, most studies in young star-forming regions suffer from incompleteness both at lower masses (below 40 \( M_{\text{Jup}} \)) and in spatial content, frequently focusing on the inner regions of clusters. It is therefore unknown whether, as one moves to lower masses, other formation mechanisms take over (e.g., Whitworth et al. 2010). At the same time, the increasing capacity of numerical simulations to reproduce the collapse of entire molecular clouds is such that the comparison between simulations and observations starts to be hampered by our empirical knowledge based on small number statistics of the low-mass end of the brown dwarf regime (e.g., Bate 2009). Extensive studies of the lowest mass populations in different environments and stages of evolution are therefore required to address these questions.

To that end, several large photometric surveys are taking place to identify candidate brown dwarfs in various young clusters: for example, the Galactic Cluster Survey (GCS) (e.g., Lodieu et al. 2011), part of the Infrared Deep Sky Survey (UKIDSS, Lawrence et al. 2007) at the UKIRT (United Kingdom Infrared Telescope), the SONYC survey (Substellar Objects in Nearby Young Clusters) (e.g., Scholz et al. 2009), or our WIRCam/CFHT (Wide Field IR Camera at the Canada France Hawaii Telescope, Puget et al. 2004) survey of nearby star-forming regions (e.g., Burgess et al. 2009), among other substellar studies of targeted clusters (e.g., Bayo et al. 2011, Béjar et al. 2011). Spectroscopic confirmation of photometric candidates in all the regions is needed, however, to construct an unbiased IMF, since the contamination by field dwarfs, giants, or even galaxies at the faint magnitude ranges being probed is known to be high. This is the motivation behind the observations...
presented in this work. From the initial list of 110 brown dwarf candidate members of ρ Oph uncovered through the WIRCam survey (Alves de Oliveira et al. 2010), we had confirmed spectroscopically seven new members in our previous pilot study, six of which were classified as brown dwarfs and one very low mass star. Here, we present the results of an extended spectroscopic follow-up of 34 additional targets. With this survey, we have observed spectroscopically 70% of our candidates that fall within the photometric completeness limit of the WIRCam survey, and are nearly complete (~93% of candidates observed) down to a few Jupiter masses, through a visual extinction of 20 mag.

In Sect. 2 we describe the new spectroscopic observations and data reduction procedure. Section 3 explains the method adopted for deriving the spectral type and extinction for each candidate member, and the final results are presented in Sect. 4. We discuss the properties of the newly found members and their comparison to the cluster’s population through Sects. 5 and 6, and present the final conclusions in Sect. 7.

2. Observations and data reduction

2.1. The ISAAC / VLT spectroscopic follow-up

We have conducted a near-infrared (near-IR) spectroscopic follow-up of 34 targets from our WIRCam/CFHT list of candidate members of ρ Oph, randomly selected with magnitudes brighter than the WIRCam survey completeness limits at J=20.5 and H=18.9 mag, and through a visual extinction of approximately 20 magnitudes (see Sect. 6.4.1 and Fig. 9). We additionally observed five previously known brown dwarfs with spectral types determined in the optical, which we use to test our analysis methods (see Tables 1 and 3). The observations were carried out in visitor mode from 4 to 6 May 2010 with ISAAC (Infrared Spectrometer And Array Camera, Moorwood et al. 1998) mounted on the Unit Telescope 3 (UT3) of the VLT, Paranal (Table 1). Each target was observed with the low-resolution grating in the short wavelength arm of ISAAC and a long slit with a width of 0.6” or 0.8” to better match the seeing conditions. Given the faint J magnitudes of most of the targets, observations were done only in the H (1.42–1.82/µm) and K (1.82–2.5/µm) bands. Individual exposure times were scaled to the target’s brightness and night conditions, and repeated in an ABBA pattern to allow for sky subtraction. The slit position was aligned with the parallactic angle, except for targets CFHTWIR-Oph 20 and 98, which were aligned with a nearby faint target. Standard A0 stars were observed at regular intervals during the night disk.

The data was reduced with IRAF (Image Reduction and Analysis Facility) for all targets by following standard procedures. The 2D spectra were flat-fielded and corrected for bad pixels, after which the sky subtraction was done by subtracting adjacent pairs of spectra. The spectra were corrected for distortions along the spectral and spatial directions, wavelength-calibrated, and then aligned and co-added. Individual frames where the spectrum was strongly affected by bad pixels or cosmic rays were removed before the co-adding operation. The exposure times per individual integration and the final number of combined frames for each target are given in Table 1. Each spectrum was extracted with the APALL routine in IRAF. Each extracted spectrum was further divided by that of the standard A0 stars observed at similar airmass to remove the telluric absorptions, and the relative flux recovered by multiplying it by a theoretical spectrum of an A0 star (Pickles 1998, taken from the ESO webpage). A linear interpolation was made to remove the strong intrinsic hydrogen absorption lines from the spectra of the A0 standard stars, across the lines that are more predominant at this resolution (the Brackett series lines at 1.54, 1.56, 1.57, 1.59, 1.61, 1.64, 1.68, 1.74, 2.17/µm). To calibrate the relative fluxes of the spectra originating from the two grisms, we calculated the pseudo spectral flux for each band by convolving the spectra with the respective WIRCam transmission curves and integrating the flux, which are then compared to the flux ratios for H and K bands measurements of the WIRCam photometry, and scaled accordingly.

2.2. The Osiris / GranTeCan observations

We obtained optical spectra for three targets from the WIRCam survey; two of them were also observed in the near-IR during the ISAAC/VLT run previously described (CFHTWIR-Oph 30, 31), while the other had been observed with SoFi/NTT and presented in our survey paper (Alves de Oliveira et al. 2010). The targets were observed with OSIRIS (Cepa et al. 2000), a spectrograph operating from 0.365 to 1.05/µm, mounted on the Gran Telescopio Canarias (GTC), the 10.4 m telescope at the Observatorio del Roque de Los Muchachos (La Palma, Canary Islands). We obtained low-resolution spectroscopy for all targets with the R300R grism and an 1” slit aligned with the parallactic angle. The observations were obtained in service mode on 22 and 23 May 2010, as well as the spectro-photometric standards, flats, bias, and arcs necessary for the calibrations. Each target was observed with two exposures of 450 s each for CFHTWIR-Oph 31 and 96, and 1500 s for CFHTWIR-Oph 30. The data was reduced using standard IRAF routines, including bias subtraction, flat-field correction, extraction of the 1D spectrum, and wavelength calibration. The instrumental response was corrected using spectrophotometric standards, and the individual spectra were median-combined.

3. Methods

3.1. Spectral classification in the near-IR

It has been shown by several studies that low-resolution near-IR spectroscopy can be used to accurately determine spectral types of young stellar objects and confirm their low gravity (e.g., Allers et al. 2007, Weights et al. 2009). One of the most evident youth indicators is the water vapour absorption bands that result in the triangular shape of the H-band (Luhman & Rieke 1999, Lucas et al. 2001, McGovern et al. 2004), with a peak redwards of that of field dwarfs that instead show a plateau at the same wavelength range. The same effect of H₂O absorption is seen in the K band (>2.3/µm), where CO absorption is also present. Provided the spectrum has a reasonable signal-to-noise ratio (S/N~30), the Na I feature at 2.2/µm can be used as a youth indicator, since it is less prominent in young objects than in field dwarfs. Finally, near-IR emission lines characteristic of outflows (e.g., H₂ 1–0 (S(0) emission at 2.12/µm) or accretion (e.g., hydrogen recombination line Brγ at 2.16/µm) can be detected even at low resolution and provide further evidence of the membership and youth of a candidate. In this section, we describe the methodology developed to investigate the nature of the candidate members of the ρ Ophiuchi cluster.

3.1.1. Empirical grid of template spectra

To derive the spectral type and extinction of the candidate members observed with ISAAC, we compare each spectrum to an em-
Table 1. Journal of the observations.

|            |          | 104 (120×6, 60×6)   |                                    |
|            | 0.8      | 58 (60×2, 60×4)     | TWA 26 (60×8, 60×8)                |

(a) Exposure times are given in seconds per individual integration, times the number of total integrations for the H and K grisms, respectively.

An analogous grid was constructed that is composed of field (1-5 Gyr) template spectra of G and K stars [Rayner et al.].
3.1.2. Fitting technique

For each candidate spectrum, we determine the best fit in spectral type and extinction by minimizing a goodness-of-fit statistic between the candidate and each template (Cushing et al. 2008), defined as

$$GF = \sum \frac{w_j}{A} \left( \frac{f_{\lambda}^{\text{candidate}} - f_{\lambda}^{\text{template}}}{\sigma_{\lambda}^{\text{candidate}}} \right)^2$$

where $w_j$ is the weight of each spectral element (taken as its spectral width as in Cushing et al. 2008), $f_{\lambda}$ and $F_{\lambda}$ are the flux densities of the candidate and template, respectively, and $\sigma_{\lambda}$ is the noise for the candidate spectrum. Regions of the spectrum dominated by telluric absorption were excluded from the fit, which was done over the wavelength ranges 1.45–1.8 and 2–2.45 $\mu$m. Since the ISAAC spectra cover only the $H$ and $K$ bands, we have used the photometric point of the $J$ band in the fit, which is compared to the spectro-photometric magnitude derived by each template in the grid, and given a weight that is the sum of the individual weight values in the $J$ band of the template. This approach is necessary in order to minimise the effect the degeneracy between extinction and spectral type have on the overall slope of a young late-M and L-type spectrum (e.g., Allers et al. 2007).

3.1.3. Testing the fitting method

We tested this technique by determining the near-IR spectral type and extinction for the 30 aforementioned confirmed young members of Taurus and IC 348, where the $J$-band part of each spectrum is replaced by its integrated flux to mimic our ISAAC dataset. The vast majority of the derived spectral types agree to within one subclass in respect to their published optical spectral type. Furthermore, particular geometries of disks around the brown dwarfs could cause variability at near-IR wavelengths, as well as contribute to the $K$-band overall flux, which would impact the extinction derived, but not significantly affect the overall spectral features. Table 3 summarises the properties of these objects as retrieved from the literature, as well as the parameters derived from our spectral fitting method.

3.2. Spectral classification in the optical

The most distinct feature in the optical spectra of M dwarfs are the absorption bands from titanium oxide (TiO) and vanadium oxide (VO), which are very sensitive to temperature, increasing in strength as we move to later spectral types in a smooth progression (e.g., Kirkpatrick et al. 1993). To determine the spectral type and extinction of our targets, we employ the same algorithm as is described in the previous section, using the goodness-of-fit statistic to determine the best match between the candidate member and the grid of templates. The grid is composed of young objects that are members of Chamaeleon (~1Myr, Luhman 2004a), which have been shown to be suitable for relative spectral classification of young M dwarfs in star-forming regions (see Table 2 in Riddick et al. 2007). The templates are reddened progressively in steps of 0.1 visual magnitude, using the extinction law of Fitzpatrick (1999). The typical errors of this method in the spectral type domain we are studying (late M to early L) are of the order of 1 subclass in spectral type and 1 magnitude of extinction (e.g., Guieu et al. 2006, Riddick et al. 2007).

4. Results

The numerical spectral fitting technique has been applied to all candidate members observed with ISAAC/VLT and Osiris/GTC, and the solution for spectral type and extinction is summarised in Table 4.
Table 2. Empirical grid of young template spectra.

4.1. New spectroscopically confirmed members of \( \rho \) Oph

By applying the numerical spectral fitting technique to all spectra, we classify 20 of the observed targets as new young members of the \( \rho \) Ophiuchi cluster, with spectral types between M3 and L4. An additional target, CFHTWIR-Oph 96 had been previously classified as a member through near-IR spectroscopy (M8.25, \( A_V=1.10 \) mag. **Alves de Oliveira et al. 2010**). In this work, we derive a more accurate optical spectral type (M7.75, \( A_V=2.4 \) mag), which agrees, within the errors, with the near-IR spectral type. We classify 14 targets as likely contaminants.

4.1.1. Membership

The youth of each target, hence membership, was assigned based on the presence signatures of low-gravity or/and accretion disks, as well as each target’s spatial location in relation to the cloud environment. For that end, the results from the spectroscopic follow-up were complemented with the available information in the literature, most of which had already been described and summarised in Table 1 of the WIRCam survey paper of \( \rho \) Oph (**Alves de Oliveira et al. 2010**). For targets with a near-IR spectral type later than \( \sim M3 \), the shape of the vapour absorption bands has been matched to that of spectra of young stellar objects with low gravity, providing a clear indication of their youth (denoted as \( H_2O \) in Table 3). The detection of mid-IR excess in the Spitzer photometry consistent with that expected for young objects surrounded by disks (\( ex \) in Table 3) is another indication of membership. For these objects, accretion might still be on-going, so any signatures of \( Br_\gamma \) emission are also indicative of youth, as well as \( H_2 \) emission arising from outflows. Furthermore, all objects selected as members do not show any sign of Na I absorption, which is consistent with them having low gravity. Finally, the spatial location of an object also contains relevant information of whether it belongs to the cloud or not. For targets that do not show strong IR excess, the extinction derived in the numerical spectral fitting is not contaminated by the contribution of a disk, and should reflect the position of the target in respect to the depth of the cloud. We compared that value to the extinction map of the Ophiuchus cloud provided by the COMPLETE project ([Ridge et al. 2006](http://www.cfa.harvard.edu/COMPLETE)), computed with the NICER algorithm ([Lombardi & Alves 2001](http://www.cfa.harvard.edu/COMPLETE)), using data from the Spitzer Legacy Program "From Molecular Cores to Planet Forming Disks" ([Evans et al. 2003](http://www.cfa.harvard.edu/COMPLETE)). The extinction provided by the map is determined over a beam that is larger than our target observations and also over the entire depth of the cloud. Nonetheless, it still provides a good estimate of the environment for each candidate. All of our candidate members (except CFHTWIR-Oph 101, see discussion below) have extinctions that place them inside the cloud, when compared to the Spitzer extinction map. That is not the case, for example, for the M dwarfs we listed in Table 3 as likely contaminants, which have extinctions equal to or even greater than the expected values for the respective location placing them behind the cloud.

From the targets classified as members, sixteen (CFHTWIR-Oph 16, 18, 30, 31, 37, 53, 56, 58, 66, 78, 90, 96, 98, 103, 104, 107) show mid-IR excess indicative of a disk, as well as spectral features consistent with low gravity, which we con-

consider the most constraining clues to their membership. In addition, five from those (CFHTWIR-Oph 16, 30, 56, 66, 78) have the near-IR variability typical of young stellar objects (Alves de Oliveira & Casali 2008). The membership of the five targets without mid-IR excess (CFHTWIR-Oph 9, 33, 77, 100, 101) is assigned based on complementary diagnostics and discussed below in more detail.

CFHTWIR-Oph 9, 33, 77: Candidate 9 is located in a region of the cloud with high extinction (A_V=17 mag), and the derived extinction value for this object is A_V=6.6 mag, clearly placing it in the middle of the cloud. Its K band spectra also clearly show the CO overtones characteristic in spectra of early L dwarfs, which is consistent with its near-IR and optical photometric colours.

CFHTWIR-Oph 33 is located close to the core of the cloud in a region with an A_V=24 mag, this target shows very peaked H and K band spectra characteristic of young objects, and with an A_V=3.6 mag it is definitely not a background source. It is too bright to be a late L foreground field dwarf that its spectra indicate, further confirming its membership to the cluster. Similar to these two targets, CFHTWIR-Oph 77 is located in an area of high extinction (A_V≈25 mag), and following the same argumentation, both the derived A_V and spectral type are consistent with it being a member of the cloud. It could not be reproduced by any of the templates in the grid of field dwarfs. The spectral classification of this target is discussed further in Sect. 4.1.2.

CFHTWIR-Oph 100 and 101: The target 100 is in a region of relatively low extinction (A_V=5-8 mag), which places the object at the further edge of the cloud, when compared to the extinction derived by numerical fitting (A_V=8 mag). When redreddening the colours of the target by this amount, the object still lies confidently above the main-sequence and is rather consistent with the expected colours of an early L young brown dwarf. The signal-to-noise ratio in the K band is not enough to make a definite assessment of the Na I feature. The CO overtone absorptions in the K band further support its late spectral type, which again would be too bright to be a field dwarf behind the cloud. CFHTWIR-Oph 101 is the only target we classified as a member for which the derived extinction value exceeds that expected for the region

(a) Name as in Alves de Oliveira et al. (2010), where additional information regarding each target is included. (b) Based on the tests performed to the spectral fitting method, uncertainties on the spectral type and A_V are estimated as 1 spectral subclass and 1 mag, respectively. (c) See Sect. 6.2 where the temperature scale applied is explained. (d) See Sect. 4.1.2 for the discussion.
Fig. 2. ISAAC/VLT low-resolution spectra of the new confirmed members in ρ Oph. All spectra are corrected for extinction with the values found through the numerical fitting procedure.

Fig. 3. ISAAC/VLT low-resolution spectra of the members with uncertain spectral type.

from the extinction map. When looking at the near-IR images, it is, however, clear that differential extinction is present, since this part of the cloud shows a ridge-like structure. The target sits on one of the dense ridges, which seems to explain the high extinction, and has most likely been smoothed in the low spatial resolution of the extinction map. There is no indication of Na I absorption, further supporting its low-gravity, while there is an indication of Brγ emission (2.16 μm) showing that accretion may be on-going. Finally, the peaked shape of the H band is not reproduced by any spectra of the grid of field dwarfs. Based on these arguments, we classify both targets as members of the ρ Ophiuchi cluster.

4.1.2. Comments on individual sources

CFHTWIR-Oph 30: The candidate member CFHTWIR-Oph 30 has been previously associated with the cloud by several diagnostics, including mid-IR excess emission consistent with that of YSOs (e.g., Bontemps et al. 2001; Gutermuth et al. 2009) and X-ray emission (Gagné et al. 2004). More recently, Alves de Oliveira & Casali (2008) found this object to show extreme variability in the near-IR, with a brightening of 3.5 magnitudes in the K band in only one year, which the authors suggest could indicate an EXor-type object, a class of young variable stars where the large magnitude variations are thought to be caused by massive infall of circumstellar material onto the central star (e.g., Herbig 2008). Based on the acquisition images of the ISAAC dataset, we have estimated a magnitude of K = 14.54 ± 0.3, which would indicate that in 2010 the target was again approaching its minimum state. As a result, the necessary spectroscopic integration times have been underestimated and the signal-to-noise of the ISAAC spectra is too low for a reliable spectral fitting. This is underpinned further by the large uncertainty of the near-IR magnitudes at the time of the spectroscopic observations, crucial for calibrating the relative spectral fluxes of the various bands. This target was also observed spectroscopically in the near-IR by Geers et al. (2011) (source #3 in their Table 1) and classified as non-substellar. We obtained an optical spectrum of CFHTWIR-Oph 30 with GTC, allowing more reliable analysis. We derive a spectral type of M3.5 with a visual extinction of 4.7 magnitudes (see Fig. 4).
There is no indication of Hz emission in the optical spectrum, which could support the scenario where the YSO is at its rest accretion state.

We have compiled the available IR measurements from the literature, which are described in the following articles: Barsony et al. (1997), SQIID/KPNO, Cutri et al. (2003) 2MASS, Alves de Oliveira & Casali (2008) WFCAM/UKIRT, Alves de Oliveira et al. (2010) WIRCam/CFHT, Geers et al. (2011) MOIRCS/Subaru, Gutermuth et al. (2009) IRAC/Spitzer, and Wright et al. (2010) WISE. The resulting light curve for the different bands is shown in Fig. 3. Even though we did not correct the magnitudes to account for the differences between photometric systems, this cannot account for the large amplitude that is seen, and it can only be explained by intrinsic variability. This plot strengthens the rare colour effect already measured by Alves de Oliveira & Casali (2008), with the star bluer when fainter and the cause of variation possibly related to the star’s disk. For example, as a clump of material or warp in the disk moves out of the observers line-of-sight, the star-disk system becomes fainter in the IR since less light is being absorbed and reprocessed by the circumstellar disk. Disks radiate strongly at longer wavelengths, so when the warped inner disk region rotates out of the observed fraction of the star, the stellar colours become bluer, approaching its intrinsic colours. However, the intrinsic fluxes of an M3.5 YSO are much brighter than what is observed at its minimum. Indeed, its optical spectral type would indicate that the nominal state of the target is at its brightest stage. If taking this into account, the variability could instead be explained by a companion object, since the percentage of coverage of a cold spot on the surface needed to reproduce such behaviour is not physical when considering the magnitude variations. Then, the observed behaviour could be due to a system consisting of two objects with similar spectral type (i.e., similar intrinsic luminosity), one having strong IR excess and undergoing variable circumstellar extinction by the disk (i.e., close to edge-on), the other component either disk free or at least not obscured by its disk (e.g., different inclination). Then, the whole system would become fainter in the near-IR when the disk obscures the primary. At that time the secondary would start to dominate the near-IR integrated light. If the secondary has no (or a smaller) IR excess, its near-IR colours will be bluer than that of the primary, and the system would in turn become bluer when fainter in the near-IR. A detailed modelling of the system is beyond the scope of this paper, and will most likely be addressed by dedicated monitoring surveys such as YSOVAR [1] (Morales-Calderón et al. 2011).

CFHTWIR-Oph 37, 66, 77: For all the targets we analysed, the near-IR numerical fit is done both with the J band photometric point and without it, for which we obtain the same solution, confirming that the spectral shape of the H and K bands is the dominant component of the fit, as opposed to the JHK colours on which the spectra are calibrated. This is, however, not the case for three targets (CFHTWIR-Oph 37, 66, 77) where we obtained two different solutions depending on whether or not we included the comparison between the J photometric point of the target to the integrated flux of the template’s J spectra in the fit. The different solutions are in fact correlated, since they are extreme cases of the degeneracy between extinction and spectral type, which exists at this low resolution (e.g., Allers et al. 2007), and also at a modest signal-to-noise of the targets. In the case of CFHTWIR-Oph 37 and 66, their spectral energy distribution (SED) shows a strong IR excess up to 24 μm, meaning the contribution from the disk emission could affect the determination of the extinction. If we investigate their near-IR colours, CFHTWIR-Oph 37 is consistent with the earlier spectral type solution (M5.75, A_V=23.4 mag), while the faint magnitudes of CFHTWIR-Oph 66 are in agree with the later spectral type solution (M7.75, A_V=15.1 mag). We adopt these classifications throughout the rest of the paper. CFHTWIR-Oph77 does not show mid-IR excess, and its colours are consistent with a later spectral type, which is also supported by the appearance of the CO overtone absorption in its K band spectra, and therefore we adopt the spectral type solution M9.75 with A_V=10.0 mag. CFHTWIR-Oph 53, 56, 58, 104: These targets are assigned a spectral type that carries a larger uncertainty than the other candidates, due to both the poor signal-to-noise ratio and strong mid-IR excess (see Fig. 3). CFHTWIR-Oph 53, 58, and 104 show strong water vapour absorption in the H band, as well as pronounced CO overtone absorption in the K band, and are largely consistent with a late M to early L spectral type. The signal-to-noise in the H band is too low to assess the quality of the fit, and the solutions presented rely mainly on the K band features. CFHTWIR-Oph 56 appears to have an earlier spectral type than M3, the hottest template in our grid. They all have clear signatures of youth and are certainly members of the cluster. We include the best spectral solution found in Table 4, but caution that the error in spectral type is significantly higher than for the other targets. We take a conservative approach and do not include them in the analysis of the brown dwarf population in Sects. 5 and 6.

Fig. 5. Light curve for CFHTWIR-Oph 30 combining all the IR measurements available (SQIID/KPNO, 2MASS, WFCAM/UKIRT, WIRCam/CFHT, MOIRCS/Subaru, IRAC/Spitzer, and WISE), where uncertainties are typically ≤0.1 mag. The magnitudes have not been corrected to a unique photometric system, though this cannot account for the large variations that can only be explained by intrinsic variability.
4.2. Likely contaminants

We classify fourteen candidates in our sample as contaminants, which are most likely background giants or field M dwarfs. All these targets (CFHTWIR-Oph 1, 3, 6, 7, 12, 15, 17, 19, 20, 22, 28, 42, 52, and 69) have a non-negligible amount of extinction, so they cannot be foreground stars. For most of the targets (CFHTWIR-Oph 1, 6, 7, 17, 19, 20, 22, 28, 42, 52), there is no sign of water absorption features in their spectra, implying a spectral type that is earlier than M3. However, a young object (~1Myr) at the distance of ρ Oph (~130 pc), ought to be much brighter than the faint magnitudes these targets show. Therefore, they are most likely giants and AGB stars, also known to have mid-IR excess, which are seen through the cloud. The targets classified as field M dwarfs (CFHTWIR-Oph 3, 12, 15, 69), show spectral features that are better matched by our grid of template field dwarfs, such as a plateau in the shape of the $H$ band, and the Na I absorption feature characteristic of older objects. Furthermore, they do not show any other sign of youth, such as mid-IR, and all have extinction solutions that place them behind the cloud when compared to those predicted by the extinction maps.

4.3. Effectiveness of the photometric selection

We combined the results for all the candidate members selected in our WIRCam/CFHT survey that have been observed spectroscopically. These include seven confirmed members presented in our previous spectroscopic follow-up (Alves de Oliveira et al. 2010), where we found four contaminants (these were excluded from the list of candidate members of the cluster). Furthermore, McClure et al. (2010) confirm the membership of six of our candidate members. In this study, we have confirmed as members of the cluster 20 additional targets. The candidates classified as contaminants total 18. In absolute terms, this implies a success rate of 65%. If we take all the candidate members within our photometric completeness limits into account (see Fig. 9), by including 17 targets that have not been observed spectroscopically, we derive lower and upper limits of the success rate of the WIRCam/CFHT survey of ρ Oph of 49% and 74%, respectively. This agrees with previous estimates in surveys of other clusters (e.g., Oliveira et al. 2009, Scholz et al. 2009, Lodieu et al. 2011), reinforcing the need for spectroscopic confirmation of candidate members selected from photometry and the limitations of previous IMF studies based only on photometric selected samples.

5. The brown dwarf population in ρ Ophiuchi

5.1. An updated census

Despite being one of the closest and youngest star-forming regions where brown dwarfs should be more easily detected, the high and variable extinction of the ρ Ophiuchi cluster has meant that its substellar population remained largely unknown. We compiled a list of all brown dwarf members of ρ Oph confirmed spectroscopically to date, which is an updated version of Table 4 in Alves de Oliveira et al. (2010). At the age of ρ Oph (~1Myr), the evolutionary models of the Lyon group, combined with the empirical temperature to spectral type relation determined by Luhman et al. (2003b), imply that the mass limit for hydrogen burning corresponds to a spectral type of ~M6.25 (Luhman et al. 2007). Given the limited accuracy in near-IR low-resolution spectroscopy, typically of one subclass, members classified with a spectral type of M6 are listed in the table of brown dwarfs as members at the substellar limit. To be consistent with other studies of star-forming regions and to facilitate comparison of properties across different populations, we label young objects with spectral types later than M6 as brown dwarfs. By this criterion, at the time of the latest review of the cluster (Wilking et al. 2008), only 11 brown dwarf members were known in Ophiuchus. With the WIRCam survey and the subsequent spectroscopic follow-up (Alves de Oliveira et al. 2010, and this work), we have confirmed 19 new brown dwarfs (22 if we include CFHTWIR-Oph 53, 58, and 104, which have uncertain spectral types between late M and early L), a threefold increase in the substellar population of ρ Oph. Based on the optical classification of Comerón et al. (2010), we do not include GY 10 (M5.5) in the substellar census and update the spectral type of GY 11. Other recent contributions to the census of the cluster have been done by McClure et al. (2010), where spectral types were derived up to M6 for several members, and the confirmation of one brown dwarf member by Geers et al. (2011).

* Spectral types determined from the following studies: 1. Luhman et al. (1997); 2. Wilking et al. (1999); 3. Luhman & Rieke (1999); 4. Cushing et al. (2000); 5. Natta et al. (2002); 6. Wilking et al. (2005); 7. Alves de Oliveira et al. (2010); 8. McClure et al. (2010); 9. Comerón et al. (2010); 10. Geers et al. (2011).
Table 5 lists the 29 brown dwarfs and 13 very low-mass stars at the substellar limit members of the cluster with spectroscopic confirmation known to date with coordinates and near-IR photometry, which we adopt in the following sections to study their properties. The $JHK_s$ photometry provided for each member is from the WIRCAMS/CFHT survey (Alves de Oliveira et al. 2010), except for members that were saturated or out of the field of view, for which we have listed 2MASS photometry. For each member, the spectral type and $A_V$ are shown as compiled from the literature or derived from the numerical spectral fitting in this work. We have mid-IR photometry from the Spitzer space telescope, taken by the C2D legacy project (Evans et al. 2003, From Cores to Disks), which mapped the $\rho$ Ophiuchi molecular cloud with Spitzer’s Infrared Camera (Fazio et al. 2004, IRAC) in the 3.6, 4.5, 5.8, and 8.0 $\mu$m bands over a region of 8.0 deg$^2$ and with the Multiband Imaging Camera (Rieke et al. 2004, MIPS) in the 24 and 70 $\mu$m bands over a total of 14.0 deg$^2$ (Padgett et al. 2008). The data were retrieved from the C2D point-source catalogues of the final data delivery (Evans & C2D Team 2005), using the NASA/IPAC Infrared Science Archive. All fluxes were converted to magnitudes using the following zero points: 280.9±4.1, 179.7±2.6, 115.0±1.7, 64.1±0.94 (Jy), for the 3.6, 4.5, 5.8, and 8.0 $\mu$m IRAC bands, respectively, and 7.17±0.11 (Jy) for the 24 $\mu$m MIPS band. The Spitzer catalogues were merged with the WIRCAMS/2MASS catalogue, requiring the closest match to be within 1″. A counterpart was found for all substellar members, which were detected in one or more mid-IR bands. Only detections above 2 $\sigma$ were kept, though all objects have 7 $\sigma$ detections in the [3.6] and [4.5] bands.

5.2. Slopes of the spectral energy distributions

The disk population of the $\rho$ Ophiuchi has been studied in great detail (e.g., Natta et al. 2002, Andrews & Williams 2007, Furlan et al. 2009, Andrews et al. 2010, Ricci et al. 2010, Cieza et al. 2010, McClure et al. 2010). It is found that, despite the young age of the cluster ($\sim$1-1.5 Myr), many circumstellar disks in $\rho$ Oph are evolving showing features such as millimeter size dust grains in the outer disk region (Furlan et al. 2009, Andrews et al. 2010, Ricci et al. 2010), inner opacity holes characteristic of transition disks (Cieza et al. 2010), dust settling, and dust grain processing (e.g., McClure et al. 2010). In this section, and in light of the newly discovered substellar members in our survey, we use SEDs to classify the evolutionary state of each object. The slope of the SED ($\alpha$ is the spectral index) is used to distinguish YSOs into various classes according to their mid-IR (and millimetre) emitting energy (Lada & Wilking 1984, Adams et al. 1987, Lada 1987), representing deeply embedded YSOs (Class 0, Andre et al. 1993), embedded YSOs still surrounded by an envelope (Class I), YSOs possessing a circumstellar disk (Class II), flat-spectrum sources which may represent an intermediate stage between Class I and II (FS, Greene et al. 1994), and sources with a weak or debris disk (Class III).

Following the approach of disk studies using IRAC and MIPS photometry in other young clusters (e.g., Chamaeleon I and Taurus, Luhman et al. 2008a, 2010), we computed the spectral slopes across several bands ($K_s$/[3.6], $K_s$/[24], [3.6]/[8.0], [3.6]/[24]), which allowed us to derive an SED class even for members which were not detected at 24 $\mu$m. All fluxes were first dereddened by the respective extinction value listed in Table 5 using the extinction law from Flaherty et al. (2007). We have derived in this manner the spectral slopes for 38 of the low-mass stars at the substellar limit and brown dwarf members.

Table 6. SED slopes for spectroscopically confirmed brown dwarfs in $\rho$ Oph.
Class II. Inside the Class II group are two objects that have SEDs indicative of Class I (\( \alpha \sim -0 \)). GY92 344 and CFHTWIR-Oph 66. (McClure et al. 2010) find evidence for a disk around GY92 344, so we adopt this result and classified it as Class II. CFHTWIR-Oph 66 shows only moderate excess from 3.6 to 8.0 \( \mu \)m, and is more consistent with a Class II.

Four objects that are not detected at 8 \( \mu \)m or 24 \( \mu \)m (SONYC-RhoOph-1, CFHTWIR-Oph 9, 100, 33) nevertheless have detections at other IRAC bands, which we used to constrain their SED class. CFHTWIR-Oph 100 and SONYC-RhoOph-1 are detected in the three other IRAC channels. In the IRAC colour-colour diagram [3.6]-[4.5] vs. [4.5]-[5.8], both objects occupy the same region of the Class III objects, not showing a significant excess in any of the colours. Based on this evidence, we classified them as likely Class III (denoted as III?). CFHTWIR-Oph 9 and 33 are only detected at 3.6 and 4.5 \( \mu \)m. In the colour-colour diagram \( K_s-[3.6] \) vs. [3.6]-[4.5], CFHTWIR-Oph 9 shows a clear excess mid-IR excess, so we classify it as likely Class II (denoted as II?). CFHTWIR-Oph 33 occupies a region between Classes II and III, so we cannot ascertain its SED class. Finally, CFHTWIR-Oph 18 is detected at 3.6 \( \mu \)m but has a 2\( \sigma \) detection at 8.0 \( \mu \)m. The slope of the SED shows it has strong mid-IR excess, which places it in the Class I/Class II range, though given the limited information at mid-IR wavelengths this classification remains provisory (denoted as II?).

According to the SED classifications, 68\( \% \) of the brown dwarf members of \( \rho \) Oph are Class II sources, i.e., have an SED representative of a disk. Statistical errors are calculated following the method proposed in Burgasser et al. (2003). If we also include all objects at the substellar limit (spectral type \( \sim \)M6), the percentage of Class II sources goes up to 76\( \% \). The disk frequency in the stellar domain of \( \rho \) Oph has been estimated as 27\( \pm \)5\( \% \) for an extinction-limited sample of \( \Delta V \leq 8 \) and representative of YSOs with masses \( \geq 0.2 \, M_\odot \) (Erickson et al. 2011). We considered the substellar members that lay within the same extinction limit (see Fig. 9), and derived a disk fraction of 74\( \% \)\( \pm \)12\( \% \), confirming the large number of brown dwarfs with disks in this cluster. Luhman et al. (2011) have found the disk fraction in Taurus (~1 Myr) to be 75\( \% \) for objects with \( \geq 0.3 \, M_\odot \), and 45\( \% \) for low-mass stars and brown dwarfs. By comparing these results to the disk fraction in IC 348, Cha I, and \( \sigma \) Ori, the authors suggest stars with masses greater than 0.5 \( M_\odot \) members of dense clusters have shorter disk lifetimes. The results of the disk fraction of the stellar population derived by Erickson et al. (2011) also support this hypothesis. The disk fraction we derive for brown dwarfs (\( \geq \)M6) is higher than what is found, for example, in \( \sigma \) Ori (60\( \% \), Luhman et al. 2008b), IC 348 (51\( \% \), Lada et al. 2006, Luhman et al. 2008a), and Cha I (44\( \% \), Luhman et al. 2008b). A detailed analysis of the disk fraction per spectral type for the \( \rho \) Ophiuchi cluster across the entire mass range is needed to understand this result, though such a study is beyond the scope of this paper.

6. The Rho Ophiuchi population

To compare the properties of the population of the \( \rho \) Ophiuchi molecular cloud to other young clusters, it is fundamental to analyse this newly found population of substellar members in respect to the stellar content of the cluster. Despite being one of the closest star-forming regions, the high and variable extinction in \( \rho \) Ophiuchi and the fact that the central cluster extends over an area on sky greater than 1 deg\(^2\) means that many candidate members still lack a spectroscopic classification, hence a
reliable membership assessment. Here we summarise the information we gathered from different spectroscopic surveys.

6.1. The cluster's stellar population

We took as a starting point for the membership compilation the review done on the cluster by Wilking et al. (2008), excluding the substellar members and members with a spectral type of M6, which are at the substellar limit and have already been discussed in the previous section. To this list, we added newly found members with spectroscopic confirmation published afterwards. The literature review can be summarised as follows:

- Wilking et al. (2008): in total, the compiled list contains 316 objects, from which 27 are already included in Table 5. From the remaining 289 listed targets, 156 members have assigned spectral types from optical and/or near-IR spectroscopy and evidence of youth (please see the review for references), while 133 did not have any spectral type assigned at that time;
- Cieza et al. (2010) derived spectral types for a total of 34 sources, nine of these had previously determined spectral types, while the remaining 25 sources are located outside the central region of the cluster and were therefore not included in our compilation;
- Alves de Oliveira et al. (2010) computed spectral types for six new brown dwarfs and one very low mass star;
- McClure et al. (2010) determined spectral types for a few tenths of sources and their binary components (from which 9 are shown in Table 5, including 25 candidate members compiled by Wilking et al. (2008) which lacked spectroscopic and four sources that were not part of that list but have spectral types and membership determined in the literature. N.B., some of these spectral types had been published earlier by Furlan et al. (2009), though it is in this paper that the data reduction and analysis are presented);
- Geers et al. (2011) derived the spectral type for one new brown dwarf;
- Erickson et al. (2011) confirmed 30 new members with optical spectral types, where only three were part of the Wilking et al. (2008) compilation. They combined all the new members with 88 previously known members with optical spectral type from an analogous optical survey (Wilking et al. 2005), 14 members compiled from the literature, and three members for which they presented optical spectral types but had already near-IR spectral types determined by Luhman & Rieke (1999).

In this work we confirm spectroscopically three new members with spectral types indicative of masses above the substellar limit (besides the 13 brown dwarfs already included in Table 5 and the four members with uncertain spectral types that we do not include in this analysis); totalling a list of 250 members of the cluster where 208 have spectral types earlier than M6, and 42 have spectral types later than or equal to M6.

Several other sources have been associated with the cloud through X-rays (Imanishi et al. 2001, Gagné et al. 2004, Ozawa et al. 2005, Pililiieri et al. 2010), near-IR variability (Alves de Oliveira et al. 2010), mid-IR excess (Padgett et al. 2008, Wilking et al. 2008, Gutermuth et al. 2009, Marsh et al. 2010), and methane photometric colours (Haisch et al. 2010), but lack spectroscopic confirmation. X-ray surveys have low contamination rates, particularly when large amounts of extinction block background contaminants, though at faint magnitudes, extragalactic contamination is present. In the Wilking et al. (2008) list of candidate members, there are 51 sources that have been associated with the cloud from X-ray surveys but not confirmed spectroscopically. From these, only 11 candidates are within our photometric completeness limits, and more conservative extinction limited sample (see Sect. 6.2.1), with H-band magnitudes ranging from 9.5 to 14 mag. We therefore do not expect our results to be affected in a significant way. Candidate samples found by the other aforementioned techniques are known to have much higher contamination rates and are therefore not included in the following sections. We note, however, that the majority of these candidates are outside our most conservative extinction limited sample, as well as our completeness limits (see Sect. 6.2.1).

While this paper was in the process of revision, Muzic et al. (2011) presented spectra for 21 members of ρ Oph, 14 of which had spectral types already published in the literature and five are simultaneously discovered in this paper (CFHTWIR-Oph 9, 16, 31, 58, 78). The only objects not included in our census are CFHTWIR-Oph 58 for which we could not assign a spectral type (corresponds to SONYC-RhoOph-6 with a spectral type of M6.9 calculated from the H2O defined in Allers et al. 2007), and two low-mass stars (SONYC-RhoOph-3 and 4), which have visual extinctions greater than 8 mag (see Sect. 6.2.1). Therefore, we conclude that the results from Muzic et al. (2011) do not affect any of the conclusions of this paper.

6.2. The H-R diagram

To study the masses of the members of the cluster, we first place all the members spectroscopically confirmed in the Hertzsprung-Russell (H-R) diagram (Fig. 7). For the 208 stellar members of the cluster, we compiled information from the literature on the spectral type, \( A_V \), and near-IR magnitudes. Fourteen objects did not have any measured extinction and are not be displayed in the H-R diagram but are included in the other sections. To convert spectral types to temperature, we adopted the temperature scale from Schmidt-Kahler (1982) for stars earlier than M0, and the scale from Luhman et al. (2003) for sources with spectral type between M0 and M9.5. For the L dwarfs, we applied the scale proposed by Lodieu et al. (2008) extrapolated to the L4 spectral type. The temperatures derived in this way have an estimated uncertainty of ±150 K. The bolometric luminosity was calculated using the dereddened \( J \) magnitude, a distance to the cloud of 130 pc, and bolometric corrections from Schmidt-Kahler (1982), Kenyon & Hartmann (1995), and Dahn et al. (2003). For the most massive members with spectral type B, we plotted the luminosities derived from optical photometry by Erickson et al. (2011). Figure 7 shows all the members overlaid with NextGen and Dusty isochrones (Baraffe et al. 1998, Chabrier et al. 2000) and the isochrones from Siess et al. (2000), for 1, 3, 10, and 30 Myr.

As seen in other young clusters and associations, a large parent spread in ages is seen in the H-R diagram, with most of the members lying between the 1 Myr and 10 Myrs isochrones, and some objects already close to the 30 Myr isochrone. The age for ρ Oph has been estimated as ~0.3-1 Myr (Greene & Meyer 1995, Luhman & Rieke 1999) by comparing the location on the H-R diagram of near-IR spectroscopically confirmed members found in the central core of the L1688 cloud with pre-main-sequence evolutionary models. The proximity on the sky between the ρ Oph cluster and the southeastern edge of the Upper Sco association (which adjoins the Sco OB2 association), has been several times used to explain the high star-forming activ-
such as the presence of circumstellar emission, variability caused by photospheric spots or the inner disk, and its accretion history. Observationally, unresolved binary systems will also result in an incorrect luminosity, objects observed edge-on, as well as errors in determining extinction, which is non-negligible in this cluster. Finally, errors in the spectral type classification and the fact that we adopt the same distance to all stars will also significantly affect the position in the H–R diagram. In Fig. 7, the few objects located below the 30 Myr evolutionary track have large variability (Oph 30, see Sect. 4.1.2), while the others are Class I and Class II sources, where the circumstellar material is most likely compromising one or more parameters used in deriving their luminosity.

6.2.1. Spatially and extinction limited sample

To ensure that the properties we derive for the ρ Ophiuchi cluster are representative of its population, a sample that is spatially and extinction limited, while maximizing completeness must be constructed. In a first step, we select only targets that are contained in the WIRCam survey field (Fig. 8), since we have explored the substellar population of the cluster over this area in an unbiased way. All the selected members are plotted on the colour-magnitude diagram $H$ vs. $J–H$ (Fig. 9), where the completeness limit shown is that of the WIRCam photometric survey (Alves de Oliveira et al. 2010). In this diagram, we also plot the 1 Myr isochrone at a distance of 130 pc from the BT-Settl evolutionary model (Allard et al. 2010), which ensures a smooth transition between the stellar and substellar regimes. The 1 Myr isochrones for the NextGen (Baraffe et al. 1998) and Siess in determining extinction, which is non-negligible in this cluster. Observationally, unresolved binary systems will also result in an incorrect luminosity, objects observed edge-on, as well as errors in determining extinction, which is non-negligible in this cluster. Finally, errors in the spectral type classification and the fact that we adopt the same distance to all stars will also significantly affect the position in the H–R diagram. In Fig. 7, the few objects located below the 30 Myr evolutionary track have large variability (Oph 30, see Sect. 4.1.2), while the others are Class I and Class II sources, where the circumstellar material is most likely compromising one or more parameters used in deriving their luminosity.

6.2.1. Spatially and extinction limited sample

To ensure that the properties we derive for the ρ Ophiuchi cluster are representative of its population, a sample that is spatially and extinction limited, while maximizing completeness must be constructed. In a first step, we select only targets that are contained in the WIRCam survey field (Fig. 8), since we have explored the substellar population of the cluster over this area in an unbiased way. All the selected members are plotted on the colour-magnitude diagram $H$ vs. $J–H$ (Fig. 9), where the completeness limit shown is that of the WIRCam photometric survey (Alves de Oliveira et al. 2010). In this diagram, we also plot the 1 Myr isochrone at a distance of 130 pc from the BT-Settl evolutionary model (Allard et al. 2010), which ensures a smooth transition between the stellar and substellar regimes. The 1 Myr isochrones for the NextGen (Baraffe et al. 1998) and Siess in determining extinction, which is non-negligible in this cluster. Observationally, unresolved binary systems will also result in an incorrect luminosity, objects observed edge-on, as well as errors in determining extinction, which is non-negligible in this cluster. Finally, errors in the spectral type classification and the fact that we adopt the same distance to all stars will also significantly affect the position in the H–R diagram. In Fig. 7, the few objects located below the 30 Myr evolutionary track have large variability (Oph 30, see Sect. 4.1.2), while the others are Class I and Class II sources, where the circumstellar material is most likely compromising one or more parameters used in deriving their luminosity.
shows a broad peak at an absolute magnitude of 4 to 5. We constructed the IMF for the spectroscopically confirmed members of ρ Ophi by deriving masses from the 1 Myr evolutionary models, according to each target’s effective temperature. We did not include members with uncertain spectral types, and close binaries that are not resolved in 2MASS or WIRCam images are treated as a single object. The resulting IMF is shown in Fig. 12, and it exhibits a peak at ∼0.12 M⊙. This result also agrees with what is found for other young clusters and the field mass function, which have mass function peaking in the 0.1−0.2 M⊙ range (see, for example, Bastian et al. 2010, for a review).

More quantitatively, we can calculate the number of brown dwarf to stars, defined as R = N(0.02 ≤ M/M⊙ ≤ 0.08)/N(0.08 < M/M⊙ < 10). This ratio is of 0.09±0.04 for the AV≤8 sample (and 0.09±0.02 for all members, 0.13±0.03 for AV≤15, and 0.13±0.02 for AV≤20). This value is lower than what has been found in other 1-2 Myr old clusters (0.13 in IC 348, 0.18 in Taurus, 0.26 in Cha I, and 0.44 in NGC 1333, Luhman et al. 2003b, Luhman 2004b, 2007, Scholz et al. 2011, respectively). However, this ratio is highly dependent on the accuracy of the spectral classification at the substellar limit. As pointed out in Sect. 5, 13 members of the cluster have been classified with an M6 spectral type through near-IR spectroscopy, a technique that usually carries an error ±1 subclass. According to the evolutionary models used to determine the masses, all these objects have masses greater than ∼0.08 M⊙. A spectral type of ∼M6.25 would, however, place these objects in the substellar regime and significantly change the ratio of brown dwarfs to stars. The value derived for this ratio, if we place the members classified as M6 in the substellar domain, would then be 0.14±0.04 for AV≤8 (and 0.16±0.03 for all members, 0.19±0.04 for AV≤15, and 0.20±0.04 for AV≤20). These values agree with...
those found for the aforementioned young clusters, with the exception of NGC 1333 claimed to have an excess of brown dwarfs (Scholz et al. 2011). Given that the errors associated with the spectral type classification imply an error in the ratio of brown dwarf to stars which is higher than the purely statistically derived errors, we conclude that within these limitations, our findings agree with other young clusters, and support neither the scenario of a paucity of brown dwarfs in the cluster (Erickson et al. 2011), nor an excess of brown dwarfs down to 0.02 M⊙.

7. Conclusions
We have conducted a spectroscopic follow-up of candidate members of ρ Ophiuchi uncovered in our photometric survey. We combine the results of this study with a census of the cluster, which was compiled from the literature to provide an updated study of the YSO population of the cluster. Our findings are summarised as follows.

- The spectroscopic follow-up resulted in the confirmation of 20 new members of the cluster, from which 13 are brown dwarfs, three are low-mass stars, and four have uncertain spectral types. Combined with our previous spectroscopic follow-up, this amounts to 19 new brown dwarfs members of ρ Oph found through the WIRCam survey. Fourteen of the observed candidates are classified as likely contaminants. Within the photometric completeness limits, we find the success rate of the WIRCam survey to be between 49% and 74%.

- From the new brown dwarfs uncovered in this study, four have a spectral type of L0 and one brown dwarf is an L4. These are the first L-type objects to be found in the cluster, and according to evolutionary models, these objects have masses between ~4 and ~10 Jupiter masses, placing them amongst the least massive young brown dwarfs known to date.

- We compiled a list of confirmed brown dwarfs in the cluster and using Spitzer mid-IR photometry, we derived a ratio of disks of 76±5%. This value is higher than what is found in other young clusters, so further studies are needed to understand the implications of these result.

- A census of the spectroscopically confirmed population of ρ Ophiuchi was compiled from the literature, totalling 250 members. By constructing a spatially and extinction-limited sample, which we believe is representative of the cluster’s population, we looked at the luminosity and mass distributions. We find that the distribution of spectral types peaks at M5, similar to what is seen in IC 348 and Cha I. The mass function peaks at 0.12 M⊙, which is consistent with what is found in other clusters and the field. Taking the errors associated with the spectral type classification into account, we find a ratio of brown dwarfs to stars that also agree with the one derived for other young clusters. We therefore conclude that there is no evidence for variations in the mass function of ρ Oph when compared to other nearby young clusters.

Acknowledgements. We would like to thank Dr. Fernando Selman and Susana Cerda for the excellent assistance during the VLT/ISAAC observations. We thank Dr. Kevin Luhman for kindly providing all young template spectra used in the spectral fitting. We thank the referee for providing helpful comments and suggestions. This publication makes use of data products from the Wide-field Infrared Survey Explorer, which is a joint project of the University of California, Los Angeles, and the Jet Propulsion Laboratory/California Institute of Technology, funded by the National Aeronautics and Space Administration. It is based on observations obtained with WIRCam, a joint project of CFHT, Taiwan, Korea, Canada, France, at the Canada-France-Hawaii Telescope (CFHT), which is operated by the National Research Council (NRC) of Canada, the Institute National des Sciences de l’Univers of the Centre National de la Recherche Scientifique of France, and the University of Hawaii. It is based on observations made with the Gran Telescopio Canarias (GTC), installed at the Spanish Observatorio del Roque de los Muchachos of the Instituto de Astrofísica de Canarias, on the island of La Palma. This research made use of the SIMBAD database, operated at the CDS, Strasbourg, France. Research was partly supported by the Marie Curie Research Training Network CONStellation under grant no. MRTN-CT-2006-035890 and by the French National Research Agency under grant 2010 JCJC 0501 1.
