Do current WIMP direct measurements constrain light relic neutralinos?

New upper bounds on direct detection rates have recently been presented by a number of experimental collaborations working on searches for WIMPs. In this paper we analyze how the constraints on relic neutralinos which can be derived from these results is affected by the uncertainties in the distribution function of WIMPs in the halo. Various different categories of velocity distribution functions are considered, and the ensuing implications for supersymmetric configurations derived. We conservatively conclude that current experimental data do not constrain neutralinos of small mass (below 50 GeV).

I. INTRODUCTION

In Refs. 1234 we have discussed the cosmological properties of light neutralinos (i.e. neutralinos with a mass in the range 6 GeV \( \lesssim m_\chi \lesssim 50 \) GeV), which originate in supersymmetric schemes where gaugino-mass unification is not assumed. Actually, the most remarkable features occur for neutralinos in the mass range: 7 GeV \( \lesssim m_\chi \lesssim 25 \) GeV. Namely, for relic neutralinos with these masses, direct and indirect detection rates are considerably high, and at the level of present experimental sensitivities. Furthermore, the range of the predicted values for the rates is quite narrow, at variance with what happens for neutralinos of higher masses, where the expected rates are spread over decades.

The properties of light neutralinos with respect to WIMP direct measurements were analyzed in Refs. 2 3 4. Since then, some new results and/or analyses of previous data from experiments of WIMP direct searches have appeared 5678. In the present paper, we examine whether these new data put some constraints on the relic neutralinos of light masses.

Let us recall that the differential event rate \( \frac{dR}{dE_R} \) (\( E_R \) being the nuclear recoil energy) measured in WIMP direct searches is a convolution of the WIMP-nucleus cross section with the WIMP phase-space distribution function of WIMPs, evaluated at the Earth location. By assuming that: i) in this phase-space distribution function, spatial and velocity dependence factorize, and 2) coherent interactions dominate over incoherent ones in the WIMP-nucleus scattering (which is usually the case for relic neutralinos), one recovers the expression:

\[
\frac{dR}{dE_R} = N_T \frac{\rho_0}{m_\chi} \frac{m_N}{2\mu_1^2} A^2_\xi \sigma_{\text{scalar}} \rho \frac{E^2}{2} \rho \frac{f_{\text{ES}}(\bar{w})}{w}. \tag{1}
\]

In the previous formulae, notations are: \( N_T \) is the number of target nuclei per unit mass, \( m_\chi \) is the WIMP mass, \( m_N \) is the nucleus mass, \( \mu_1 \) is the WIMP–nucleon reduced mass, \( A \) the nuclear mass number, \( \sigma_{\text{scalar}} \) is the WIMP–nucleon coherent cross section, \( f(E_R) \) is the nuclear form factor, \( \xi \) is the fraction of the mass density of the WIMP in terms of the total local density for non-baryonic dark matter \( \rho_0 \) (i.e. \( \xi = \rho_W/\rho_0 \)), \( f_{\text{ES}}(\bar{w}) \) and \( \bar{w} \) denote the velocity distribution function (DF) and WIMP velocity in the Earth frame, respectively (\( \bar{w} = |\bar{w}| \)). It is natural to define the velocity distribution function in the Galactic rest frame \( f(\vec{w}) \) where \( \vec{w} = \vec{w} + \vec{v}_\odot \), \( \vec{v}_\odot \) being the Earth velocity in the Galactic rest frame. The Earth frame velocity \( \vec{v}_f \) is then obtained by means of the transformation: \( f_{\text{ES}}(\bar{w}) = f(\bar{w} + \vec{v}_\odot) \). It is implicitly understood that the velocity DF \( f(\vec{v}) \) is truncated at a maximal escape velocity \( v_{\text{esc}} \), since the gravitational field of the Galaxy cannot bound arbitrarily fast WIMPs. The value we adopt here is: \( v_{\text{esc}} = 650 \) km sec\(^{-1} \) 4, although we will comment on the effect of a lower value, which we will set at \( v_{\text{esc}} = 450 \) km sec\(^{-1} \) 5. Finally, the quantity \( v_{\text{min}} \) appearing in Eq. 2 defines the minimal Earth–frame WIMP velocity which contributes to a given recoil energy \( E_R \):

\[
v_{\text{min}} = \left[ \frac{m_N E_R/(2\mu_1^2)}{1/2} \right], \tag{3}
\]
where $\mu_A$ is the WIMP–nucleus reduced mass.

Eqs. (1) and (2) are the basis for deriving information on the quantity $\xi_{\text{scalar}}$ from the measurements on the differential rate $dR/dE_R$. However, this procedure implies the use of a specific WIMP distribution function, which determines both the value of the local dark matter density $\rho_0$ and the shape of the velocity DF $f(v)$.

In the present paper we first discuss how upper bounds on $\xi_{\text{scalar}}$ depend on the large uncertainties affecting the WIMP distribution functions. We then discuss what is the relevance of these upper bounds on $\xi_{\text{scalar}}$ for light relic neutralinos.

II. WIMP DISTRIBUTION FUNCTIONS

In our analysis we consider a subset of the large sample of galactic halo models which were studied in detail in Ref. [10]. Following Ref. [10], we classify the DFs into four categories, depending on the symmetry properties of the matter density (or the corresponding gravitational potential) and of the velocity dependence: A) spherically symmetric matter density $\rho_{DM}$ with isotropic velocity dispersion, B) spherically symmetric and non–isotropic models of class B, C) axisymmetric models, D) triaxial models [11, 12].

For each category, different specific models are identified. The models considered in the present analysis are listed in Table I. For a thorough definition of the different models and of the values of their intrinsic parameters, and for a detailed description of theoretical technicalities, we refer to Ref. [10]. Here we just remind that for each model we calculate, either analytically (when possible) or numerically, the velocity DF which accompanies a given matter density distribution. For the spherically symmetric and isotropic models of class A, the velocity DF is obtained by solving the Eddington equation [10, 18]. For the spherically symmetric and non–isotropic models of class B we assume the anisotropy to be described in terms of the Osipkov–Merrit parameter $\beta$ [10, 18, 19] which defines the degree of anisotropy (we fix $\beta = 0.4$). In this case, the velocity DF can be obtained by adjusting the Eddington equation [10, 18]. Axisymmetric models of class C allow the presence of a definite angular momentum. We choose them as a direct generalization of some of the models of class A: for these models, analytical solutions to the relevant generalized Eddington equation may be found. In this case, the velocity DF can be obtained by a generalization of the Eddington method [10, 18]. For the spherically symmetric and non–isotropic models of class B we assume the anisotropy to be described in terms of the Osipkov–Merrit parameter $\beta$ [10, 18, 19]. In this case, the velocity DF can be obtained by solving the adjusted Eddington equation [10, 18]. Axisymmetric models of class C allow the presence of a definite angular momentum. We choose them as a direct generalization of some of the models of class A: for these models, analytical solutions to the relevant generalized Eddington equation may be found. In this case, the velocity DF can be obtained by a generalization of the Eddington method [10, 18].
The axisymmetric models of class C are not affected by the inclusion of a co–rotation or counter–rotation effect.

For the models of class A and B, the values of \( \rho \) are the minimal ones for \( v_0 = 170 \) km sec\(^{-1}\) and \( v_0 = 220 \) km sec\(^{-1}\) (i.e. corresponding to a minimal halo contribution), while for \( v_0 = 270 \) km sec\(^{-1}\) the values of \( \rho \) are the maximal ones (referring to a maximal halo). For models of class C and D, the value of \( \rho \) is always the maximal one. The axisymmetric models of class C are not affected by the inclusion of a co–rotation or counter–rotation effect.

### TABLE II: Values of the dark matter local density \( \rho_0 \) corresponding to the three different values of the local rotational velocity \( v_0 \) and obtained from the constraints on the amount of non–halo component and on the flatness of the galactic rotational curve, for the different halo models of Table I.

| Model | \( v_0 = 170 \) km sec\(^{-1}\) | \( v_0 = 220 \) km sec\(^{-1}\) | \( v_0 = 270 \) km sec\(^{-1}\) |
|-------|-----------------|-----------------|-----------------|
| A0    | 0.18            | 0.30            | 0.71            |
| A1, B1| 0.20            | 0.34            | 1.07            |
| A2, B2| 0.24            | 0.41            | 1.33            |
| A5, B5| 0.20            | 0.33            | 1.11            |
| C2    | 0.67            | 1.11            | 1.68            |
| C3    | 0.66            | 1.10            | 1.66            |
| D1    | 0.50            | 0.84            | 1.27            |

The choice we make here for the values of \( \rho_0 \) associated to each representative value of \( v_0 \) is the following: for \( v_0 = 170 \) km sec\(^{-1}\) (which correspond to its 95% C.L. lower bound) we adopt the case of a minimal halo, in order to determine the set of less constraining upper–limits on \( \xi \sigma_\text{nucleon}^{(\text{scalar})} \), as is clear from Eq. 10. For \( v_0 = 270 \) km sec\(^{-1}\) (which correspond to its 95% C.L. upper bound) we instead adopt a maximal halo: in this case we will determine the most constraining upper–limits on \( \xi \sigma_\text{nucleon}^{(\text{scalar})} \). In the case of the central (and reference) value \( v_0 = 220 \) km sec\(^{-1}\), we adopt a minimal halo, which reproduces the standard choice \( \rho_0 = 0.30 \) GeV cm\(^{-3}\) for the isothermal sphere. These considerations apply to all models of class A and B. For the models of class C and D, for which we can rely only on analytical solutions for the velocity DF, we are forced to use always the case of a maximal halo: in fact, analytical solutions of class...
FIG. 3: Function $I(v_{\text{min}})$ for all the galactic model of Table I, other than the isothermal sphere, for $v_{\text{esc}} = 650 \text{ km sec}^{-1}$. The label which identifies the model is written in the bottom-left corner of each panel. Notations are as in Fig. 1. In panels (g) and (h), which correspond to axisymmetric models, the dotted and dashed lines refer to maximal galactic co-rotation and counter-rotation, respectively. In panel (h), the long-dashed line shows the modification of the $v_0 = 270 \text{ km sec}^{-1}$ case when $v_{\text{esc}} = 450 \text{ km sec}^{-1}$.

Let us turn now to the direct effect of the velocity DF on the detection rate, which is studied here in terms of the relevant function $I(v_{\text{min}})$ of Eq. 2. Fig. 1 shows $I(v_{\text{min}})$ for the isothermal halo and for the three values of $v_0$ listed in Table II. We see that for low values of $v_{\text{min}}$ the larger contribution to the detection rate occurs when $v_0$ is smaller, since for smaller rotational velocities the velocity dispersion of the isothermal Maxwellian distribution is also smaller, and in turn this enhances the average inverse velocity, which is related to the definition of $I(v_{\text{min}})$: $\langle 1/w \rangle = I(0)$. This can be analytically understood by remembering that for a pure isothermal sphere and a maximal halo the velocity distribution function is just an isotropic Maxwellian with velocity dispersion given by $v_0$:

$$f_A(v) = \left[\pi v_0^2\right]^{-3/2} \exp\left(-v^2/v_0^2\right); \quad (4)$$

in this case the function $I(v_{\text{min}})$ reads (in the limit $v_{\text{esc}} \to$...
$$I(v_{\text{min}}) = \frac{1}{2\eta v_0} [\text{erf}(x_{\text{min}} + \eta) - \text{erf}(x_{\text{min}} - \eta)],$$  \quad (5)

where $x_{\text{min}} = v_{\text{min}}/v_0$ and $\eta = v_0/v_0$. From Eq. (5) we see that for small values of $v_{\text{min}}$, the larger $I(v_{\text{min}})$ occurs for smaller $v_0$ because of the inverse law dependence.

On the contrary, for large values of $v_{\text{min}}$, the almost–exponential tail in $I(v_{\text{min}})$ is more severe when $v_0$ is small, and therefore the behaviour of $I(v_{\text{min}})$ with respect to $v_0$ is the opposite. This again is understood from the simple expression of Eq. (5). The regime we are considering ($v_{\text{min}} \gtrsim v_0$) asymptotically can be studied as the limit $\eta \to 0$ in Eq. (5), which gives:

$$I(v_{\text{min}}) \approx 2[\pi v_0^2]^{-1/2} \exp(-v_{\text{min}}^2/v_0^2).$$  \quad (6)

This shows the discussed behaviour as a function of $v_0$. The tail, due to the presence of a non vanishing $\eta$ in Eq. (5), is less severe than the one in Eq. (6) but nevertheless it follows the same behaviour.

Also the value of the escape velocity is relevant in the large $v_{\text{min}}$ tail of the function $I(v_{\text{min}})$. The results presented so far in Fig. 1 are obtained for a value of the escape velocity (in the galactic frame) $v_{\text{esc}} = 650$ km sec$^{-1}$. However, values as low as $v_{\text{esc}} = 450$ km sec$^{-1}$ have also been considered. A lower escape velocity implies a cut in the high $v_{\text{min}}$ tail of $I(v_{\text{min}})$ (22). This effect is shown in Fig. 1 for the central case $v_0 = 220$ km sec$^{-1}$.

The discussion on the behaviour of $I(v_{\text{min}})$ has direct impact on the direct detection rate, since $v_{\text{min}}$ is directly related to the recoil energy. Eq. (5) implies that very light WIMPs can produce recoil energies in the tens of keV range only if they possess large velocities. In this case, the detection rate for such light WIMPs will be mostly determined by the almost–exponential tail in the function $I(v_{\text{min}})$ discussed above. On the contrary, heavy WIMPs can produce recoil in the same tens of keV range by possessing much lower velocities: they will be therefore more sensitive also to the low $v_{\text{min}}$ part of the function $I(v_{\text{min}})$. The quantitative connection between $v_{\text{min}}$ and $E_R$ for a Ge nucleus and different WIMP masses is given in Fig. 2.

Finally, Fig. 3 shows the function $I(v_{\text{min}})$ for all the other halo models listed in Table I. As for the symmetric and isotropic models, we see that in the case of a power–law behaviour of the gravitational potential (model A2) or for the NFW density profile (model A5) the large $v_{\text{min}}$ tail is less suppressed, mainly for low $v_0$: this comes along with a larger predicted detection rate and it will translate into a more constraining upper limit for WIMPs lighter than a few tens of GeV. In the case of anisotropic models, we notice that the most direct anisotropic generalization of the isothermal sphere, which is a cored spherical distribution with anisotropic velocity dispersion (model B1) is the one which is more suppressed at large $v_{\text{min}}$: this has the effect of reducing the sensitivity of the detector to light WIMPs. On the contrary, the axisymmetric model with a power–law gravitational potential C3 is the one with the highest tail in the function $I(v_{\text{min}})$, and therefore more sensitive in constraining light WIMPs. We also notice that for this type of models, which possess an enhanced $v_{\text{min}}$ tail, the effect of a lower escape velocity is more dramatic: panel (h) of Fig. 3 shows the sizeable reduction of $I(v_{\text{min}})$ at large $v_{\text{min}}$ for an escape velocity $v_{\text{esc}} = 450$ km sec$^{-1}$ in the case of model C3 and $v_0 = 270$ km sec$^{-1}$.

The local matter density values $\rho_0$ of Table II and the results of Fig. 1 and Fig. 3 are the key elements which will be used in the next section to determine upper limits on the WIMP–nucleon scattering cross sections.

III. RESULTS AND CONCLUSIONS

In Refs. 22, 23, 24 upper limits on $\xi\sigma_\text{nucleon}$ are obtained by using a standard isothermal distribution func-
Fig. 4, when this is compared with the upper bound dis-

isothermal distribution, as shown by the central curve in
good degree of precision the CDMS limit for the standard
ing for instance the statistical procedure of Ref. [23].

take into account the part of the CDMS spectrum be-
tween 10 keV and 64 keV with an effective exposure
that yields a number of events compatible with zero be-
data, we extract the neutralino–nucleon cross section
play a role, and we will add them in our final discussion.

constraining ones. For very light WIMPs, with masses
of Ref. [8] (CDMS), since these turn out to be the most
discussion is performed in terms of the experimental data
employing the sample of distribution func-
tions discussed in the previous section. Our analysis and
discussion is performed in terms of the experimental data
of Ref. [8] (CDMS), since these turn out to be the most
constraining ones. For very light WIMPs, with masses
below 10 GeV, also the results of Ref. [7] (ZEPLIN) may
play a role, and we will add them in our final discussion.

In order to obtain the exclusion–plot from the CDMS
data, we extract the neutralino–nucleon cross section
that yields a number of events compatible with zero be-
tween 10 keV and 64 keV with an effective exposure
\((MT)_{\text{eff}} = 19.4 \text{ kg day}\), which corresponds to the effec-
tive exposure for \(m_x = 60 \text{ GeV}\) quoted in Ref. [8]. By
considering a Poissonian fluctuation of the expected rate,
we assume the upper bound of 2.3 events at 90% C.L. In
the calculation of the expected rate, we use Helm nuclear
form factors and a bolometric quenching factor equal to
1, as quoted by the experimental Collaboration [8]. Our
procedure for extracting the exclusion–plot is less refined
than the one adopted in Ref. [8], since it neglects the
dependence of \((MT)_{\text{eff}}\) on the WIMP mass and does not
take into account the part of the CDMS spectrum be-
tween 64 and 100 keV (which can be included follow-
ing for instance the statistical procedure of Ref. [23]).

Nevertheless our procedure allows us to reproduce to a
good degree of precision the CDMS limit for the standard
isothermal distribution, as shown by the central curve in
Fig. 4 when this is compared with the upper bound dis-
played in Fig. 39 of Ref. [8]. Therefore, in our analysis
we adopt our simpler procedure; we have checked that
adding a proper treatment of the efficiency and adopting
the statistical procedure of Ref. [23] yields quite similar
results.

The upper limits for the isothermal sphere (model A0)
are shown in Fig. 4 for the three representative values of
\(v_0\) and the corresponding choices for the local dark matter
density \(\rho_0\), as quoted in Table II. As already mentioned,
the central curve corresponds to the reference case of
\(v_0 = 220 \text{ km sec}^{-1}\) with \(\rho_0 = 0.3 \text{ GeV cm}^{-3}\). The upper and
lower curves are instead obtained for \(v_0 = 170 \text{ km sec}^{-1}\)
with \(\rho_0 = 0.18 \text{ GeV cm}^{-3}\) and \(v_0 = 270 \text{ km sec}^{-1}\)
with \(\rho_0 = 0.71 \text{ GeV cm}^{-3}\), respectively. An important effect
is obviously due to the different values of \(\rho_0\) which are
associated to the different values of \(v_0\), as discussed in
the previous Section and in Ref. [10]. However, the dif-
fERENCE in the function \(I(v_{\text{min}})\) is quite relevant in the de-
termination of the upper limits, especially at low WIMP
masses. In order to appreciate the difference in the ex-
clusion plots, we show in Fig. 5 the ratios of the upper
limits obtained with \(v_0 = 170 \text{ km sec}^{-1}\) (lower curve)
and \(v_0 = 270 \text{ km sec}^{-1}\) (upper curve) with respect to
the central \(v_0 = 220 \text{ km sec}^{-1}\) case. The dashed hori-
izontal lines show the ratios of the corresponding values
of \(\rho_0\). We can notice that at low WIMP masses the dif-
fERENCE in the exclusion plots is very large, much larger
than the naive ratio of the corresponding \(\rho_0\)’s. This is a conse-
quense of the sizable difference in \(I(v_{\text{min}})\) for large
\(v_{\text{min}}\), which is the regime relevant for light WIMPs, as
discussed before. The steep behaviour of the ratios in
Fig. 5 is a consequence of the fact that the sensitivity of
direct detection to very low WIMP masses (below about
10 GeV) rapidly vanishes.

On the contrary, at large WIMP masses, the differ-
ence in the exclusion plots is much close to what one
would expect on the basis of the difference in the \(\rho_0\) val-
ues. This is clear from our previous analysis, since for
large WIMP masses the relevant range of \(v_{\text{min}}\) is in the
100–300 km sec\(^{-1}\) range, which is where the difference
in \(I(v_{\text{min}})\) is small. We can also notice that, for large
WIMP masses, it is even possible to revert the value of
the ratio of the exclusion plots naively obtained by the
ratio of the different \(\rho_0\)’s: this is a consequence of the be-
aviour of \(I(v_{\text{min}})\) at small \(v_{\text{min}}\) discussed in the previous
Section.

Fig. 4 represents the maximal variability which oc-
curs for the isothermal sphere: this quantifies the ast-
rophysical uncertainty connected to this halo model.
Confronting the upper limits with the results obtained
for light neutralinos in supersymmetric models with-
out gaugino–mass universality [1, 2, 3, 4, 5], we can see
that while all the configuration in the mass range

![FIG. 5: Ratio of the upper limits of Fig. 4 obtained for an isothermal sphere (model A0). The upper curve is the ratio between the upper and the central curves in Fig. 4. The lower curve is the ratio between the lower and central curves.](image-url)
15 (8) GeV \leq m_\chi \leq 25 \text{ GeV} are excluded for the central (upper) values of v_0, only a small fraction are eliminated when v_0 assumes its lower bound value. Therefore, the conservative attitude which has to be taken when setting limits makes us to conclude that for the isothermal sphere, direct detection only mildly constrains the light neutralino sector of supersymmetric models without gaugino-mass universality \cite{1, 2, 3, 4}, in the 20–40 GeV mass range. Clearly the variation on the upper limits due to the difference in the halo properties has consequences also on the exploration of the supersymmetric parameter space for heavier neutralinos, as is shown in Fig. 4.

This is relevant also to gaugino-mass universal models, for which the lower bound on the neutralino mass exceeds 50 GeV \cite{24}.

The results for the other galactic halo models is shown in Fig. 6. The differences in the upper limits can be understood on the basis of the discussion on the isothermal sphere and on the properties of I(t_{min}) for the different models presented in the previous Section. We notice that some models, like C3, D1 and B5 are more constraining, while in the case of models like A1 and B1 the limits
imposed by direct detection are relatively less severe.

Finally, we report in Fig. 7 the summary of our analysis: together with the standard central isothermal sphere, we show the more (C3) and less (B1) constraining models we obtain. From the analysis of this figure, we conservatively conclude that from direct detection experiments there is currently no constraint on the light neutralino sector of supersymmetric models without gaugino universality. Should the local value of the rotational velocity beon its high range (close to $v_0 = 270 \text{ km sec}^{-1}$) direct detection could be able to set stringent limits on these supersymmetric configuration: all the mass range above 7–8 GeV (depending on the actual halo model) and below 25 GeV would be excluded. Notice that, would this be the case, also the local density $\rho_0$ would be large (above 0.7 GeV cm$^{-3}$, as discussed in Ref. [11] and shown in Table II): in this case the neutralino configurations below 7–8 GeV, which are not constrained by direct detection, would be completely excluded by antiproton searches. However, due to astrophysical uncertainties which affect the different detection rates, currently it is not yet possible to set absolute limits, neither from indirect detection techniques [2, 4] or, as shown in the present analysis, by direct detection.

Fig. 7 also shows the effect of a lower escape velocity. As discussed in the previous Section, this implies a cut in the high $v_{\text{min}}$ tail of $I(v_{\text{min}})$: this turns into a weaker sensitivity of direct detection to low–mass neutralinos. The effect is especially manifest for the most stringent models, like model C3 with $v_0 = 270 \text{ km sec}^{-1}$. For $v_{\text{esc}} = 450 \text{ km sec}^{-1}$, all neutralino models below 9 GeV are not constrained even for C3 model. For the A0 model with $v_0 = 220 \text{ km sec}^{-1}$, there is also a sizeable difference for light WIMPs, although this is not relevant for the neutralino configurations. Finally, in the case of model B1 with $v_0 = 170 \text{ km sec}^{-1}$, the lower escape velocity does not produce differences, since in the high velocity tail $I(v_{\text{min}})$ was already depressed even for $v_{\text{esc}} = 650 \text{ km sec}^{-1}$, as can be seen in Fig. 5.

For completeness, Fig. 7 also shows the upper limits we obtain, for the isothermal sphere and for the two extreme cases, for the ZEPLIN detector. We obtain for the isothermal sphere are slightly higher at low WIMP masses than the ones quoted by the experimental Collaboration [5]. We trace this effect to some differences in the analysis of the data (we do not make use of the “light response matrix” discussed in Ref. [7], since we do not have it at our disposal). Fig. 7 shows that for very low WIMP masses ZEPLIN could be slightly more sensitive than CDMS. Nevertheless, even lowering by a factor of 2 the upper limits we obtain for ZEPLIN, our conclusions on the limits imposed to light neutralinos remain unchanged.

Finally, we wish to remind that an annual modulation effect in direct detection has been observed by the DAMA Collaboration over seven years [25]. This result, when interpreted in terms of scalar WIMP–nucleus interactions, leads to an allowed region in the plane $\xi\sigma^{(\text{scalar})}_{\text{nucleon}}$ vs. $m_{\chi}$, which extends also to light WIMP masses. The DAMA Collaboration analysis of Ref. [25] takes into account the same variability in galactic halo models of Ref. [10], which is also used here. It is not possible to make direct comparison among the DAMA allowed region and the upper limits we obtain here for CDMS and ZEPLIN, since the DAMA region is the convolution obtained after varying all the galactic halo models, while the results presented here refer to single halo model. A proper

FIG. 7: The solid lines show the summary of our analysis on the upper limit on the quantity $\xi\sigma^{(\text{nucleon})}_{\text{scalar}}$ as a function of the WIMP mass $m_{\chi}$ for the CDMS detector and for $v_{\text{esc}} = 650 \text{ km sec}^{-1}$. The median line refers to the standard isothermal sphere with $v_0 = 220 \text{ km sec}^{-1}$ and $\rho_0 = 0.3 \text{ GeV cm}^{-3}$ (model A0). The upper and lower curves show the two extremes obtained in the analysis and refer to model B1 with $v_0 = 170 \text{ km sec}^{-1}$ (upper solid line) and model C3 with $v_0 = 270 \text{ km sec}^{-1}$ (lower solid line). The dashed line refers to model C3 with maximal counter–rotation of the galactic halo. The dotted lines show the ZEPLIN I limits obtained for the same galactic models. The long–dashed lines show the upper limits for CDMS in the case of a lower escape velocity $v_{\text{esc}} = 450 \text{ km sec}^{-1}$: the upper line refers to model A0, the lower one to model C3. For model B1, the limit coincides with the corresponding solid line. The colored region shows the values of $\xi\sigma^{(\text{nucleon})}_{\text{scalar}}$ for neutralino dark matter, obtained in a scan of the minimal supersymmetric model defined in Refs. [1, 2, 3, 4]. The funnel for low neutralino masses (below 50 GeV) corresponds to supersymmetric models without gaugino–mass unification.
comparison between different experimental results can be made only at a fixed galactic halo model. Notice that a convolution of our results would be just the upper curve (model B1) of Fig. 7.

As for the comparison between the light neutralinos of non–universal gaugino models and the DAMA allowed region, we comment by reminding that these light neutralinos are totally compatible with the allowed DAMA region, as we showed in Ref. [2]: they could in fact explain the annual modulation effect.

Acknowledgments

We gratefully acknowledge financial support provided by Research Grants of the Italian Ministero dell’Istituzione, dell’Università e della Ricerca (MIUR), of the Università di Torino and of the Istituto Nazionale di Fisica Nucleare (INFN) within the Astroparticle Physics Project.

[11] The class of models discussed in Ref. [10] represents a quite exhaustive summary of dark matter distributions functions as possible departures from the isothermal sphere model. Notice, however, that it does not include the possibility of non–thermal components in the $f(\vec{v})$, which could in principle modify the high–velocity tail of the velocity DF $f_{\text{DF}}$.
