Search for Technicolor Particles
Produced in Association with W Boson at CDF

We present a search for technicolor particles decaying into $b\bar{b}$, $b\bar{c}$ or $b\bar{u}$ and produced in association with $W$ bosons in $pp$ collisions at $\sqrt{s} = 1.96$ TeV. The search uses approximately $1.9 \text{ fb}^{-1}$ of the dataset accumulated in the CDF II detector at the Fermilab Tevatron. We select events matching the $W + 2$-jets signature and require at least one jets to be identified as $b$-quark jets. In the case of exactly one vertex $b$-tagged events, we apply a neural network flavor separator to reject contamination from charm and light quark jets. The number of tagged events and the invariant mass distributions of $W + 2$ jets and dijets are consistent with the Standard Model expectations. We succeed to set a large 95% confidence level excluded region on the $\pi_T$ mass v.s. $\rho_T$ mass plane.

1. INTRODUCTION

The mechanism of electroweak symmetry breaking in the standard model is still unknown. The most popular mechanism to induce electroweak symmetry breaking of the gauge theory, resulting in massive gauge bosons and fermions, are the Higgs mechanism [1]. Alternatively, there is a theory which induces the electroweak symmetry breaking by dynamically. This is a technicolor theory [2] which predicts the existence of the new strong force (technicolor) and new fermions (technifermions), and does not require elementary scalar bosons. Technicolor interact between technifermions to form the bound states (technihadrons) such as $\rho_0$, $\rho^0$, $\pi_0$, $\pi^0$, and $\omega_0$, analogous to the mesons on QCD. In $p\bar{p}$ collisions at Tevatron, one of the most likely process is $\rho_T \rightarrow W\pi_T \rightarrow l^\pm \nu b\bar{b}$ or $b\bar{c}$ or $b\bar{u}$, depending on their charge (Figure 1). In this analysis, we focus on this process with the Technicolor Straw Man Model (TCSM) [3]. With assuming the TCSM, the production cross section of these processes is the order picobarns (Figure 2).

2. DATA SAMPLE & EVENT SELECTION

For this analysis, we use a data sample corresponding to approximately $1.9 \text{ fb}^{-1}$ of integrated luminosity accumulated in the CDF II detector at the Fermilab Tevatron [4]. The events are collected with high-$p_T$ electron or muon triggers, which can detect electrons or muons with $E_T$ or $p_T > 18$ GeV. We further require the electron or muon that is isolated with $E_T$ or $p_T > 20$ GeV at offline level.

To select the $W + 2$ jets final state, we require that events have the large missing transverse energy and one or two $b$-jets. Therefore, we require that events have $E_T > 20$ GeV and exactly two jets, where jets are defined using a cone algorithm with radius $0.4$. We count jets which have $E_T > 20$ GeV and $|\eta| < 2.0$.

To reduce the background, we require that at least one jet in the event are identified as $b$-jet by the Secondary Vertex Tagging Algorithm. The secondary vertex tagging algorithm identifies $b$-jets by fitting tracks displaced from the primary vertex. This method has been used by other analyses at CDF [5, 6]. In addition, we add the Jet Probability Tagging Algorithm that identifies $b$-jets by requiring a low probability that all tracks contained in a jet originated from the primary vertex, based on the track impact parameters [7]. To be considered for double tag category, we require that events have two secondary vertex tagged jets or one secondary vertex tagged jet and one jet probability tagged jet.
95GeV jet energy scale (JES). Lepton identification uncertainty is less than 2%, trigger uncertainty is less than 1%, ISR/FSR

Figure 2: Production cross section calculated in leading-order calculations. We set the mass parameters as $m = 1$ and the mixing angle between isotriplet technipion interaction and mass eigenstates as $\sin \chi = 1/3$ in this model. For the other parameters on TCSM, we use the default value in PYTHIA. For this study, we focus on the mass region as: $m(W) + m(\pi_T) < m(\rho_T) < 2 \times m(\pi_T)$, $180\text{GeV}/c^2 < m(\rho_T) < 250\text{GeV}/c^2$ and $95\text{GeV}/c^2 < m(\pi_T) < 165\text{GeV}/c^2$ because of the kinematical threshold of $W\pi_T$ production and pair $\pi_T$ production.

For the systematic uncertainties of signal acceptance, we consider the effects from lepton identification, trigger, the $b$-tagging efficiency, initial and final state radiation effects (ISR/FSR), parton distribution function (PDF) and the jet energy scale (JES). Lepton identification uncertainty is less than 2%, trigger uncertainty is less than 1%, ISR/FSR

To increase the signal acceptance, we also make use of the exactly one $b$-tagged events with secondary vertex tagging algorithm. For the exactly one $b$-tagged events, we apply the neural network $b$-tagging algorithm to improve signal-to-background ratio by separating $b$-jets from $c$-jets or light flavor jets. This neural network $b$-tagging algorithm is used in previous analysis [6]. With using this algorithm, we can improve the purity of $b$-jets while keeping about 90% signal.

The dijet mass is reconstructed from the 2 jets in selected events. To reconstruct the $W + 2$ jets invariant mass, we need to determine the $p_z$ of the neutrino from the $W$ boson. After using the $W$ mass constraint to solve for the kinematics of the $t\nu$ system, we take a smaller value of the two $p_z$ solutions. (If there is no real solution for $p_z$, we take the real part of the complex solution.)

3. TECHNICOLOR SIGNAL SAMPLES

The signal samples are generated with the PYTHIA program [8]. PYTHIA version 6.216 implements the TCSM [3] in leading-order calculations. We set the mass parameters as $M_V = M_A = 200\text{GeV}/c^2$, the charge of up-type technifermion as $Q_V = 1$ and the mixing angle between isotriplet technipion interaction and mass eigenstates as $\sin \chi = 1/3$ in this model. For the other parameters on TCSM, we use the default value in PYTHIA. For this study, we focus on the mass region as: $m(W) + m(\pi_T) < m(\rho_T) < 2 \times m(\pi_T)$, $180\text{GeV}/c^2 < m(\rho_T) < 250\text{GeV}/c^2$ and $95\text{GeV}/c^2 < m(\pi_T) < 165\text{GeV}/c^2$ because of the kinematical threshold of $W\pi_T$ production and pair $\pi_T$ production.

For the systematic uncertainties of signal acceptance, we consider the effects from lepton identification, trigger, the $b$-tagging efficiency, initial and final state radiation effects (ISR/FSR), parton distribution function (PDF) and the jet energy scale (JES). Lepton identification uncertainty is less than 2%, trigger uncertainty is less than 1%, ISR/FSR
uncertainty is 1.8-11.6%, JES uncertainty is 2.7-11.3%, PDF uncertainty is 2.3-3.8% and b-tagging uncertainty is 4.3-17.0%, respectively.

4. Backgrounds

This analysis builds on the method of background estimation detailed in Ref. [5]. In particular, the contributions from the following individual backgrounds are calculated: falsely b-tagged events (mistag), $W$ production with heavy flavor quarks ($W + bb$, $W + cc$, $W + c$), QCD events with false $W$ signatures (NonW), top quark pair or single production ($t\bar{t}$, Single Top) and diboson production ($WW$, $WZ$, $ZZ$).

We estimate the mistag events by using the mistag probability that measured from the inclusive jets sample. Such mistag rate are obtained using negative tags, which are the tags that appear to travel back toward the primary vertex. The mistag rate derived from negative tags is due to tracking resolution limitations, but they provide a reasonable estimate of the number of false positive tags after a correction for material interactions and long-lived light flavor particles.

The number of events from $W +$ heavy flavor is calculated using information from both data and Monte Carlo samples. We calculate the fraction of $W$ events with associated heavy flavor production in the ALPGEN Monte Carlo program interfaced with the PYTHIA parton shower code [8, 9]. This fraction and the tagging efficiency for such events are applied to the number of events in the original $W +$jets sample after correcting for the $t\bar{t}$ and electroweak contributions.

We constrain the number of QCD events with false $W$ signatures by assuming the lepton isolation is independent of $E_T$ and measuring the ratio of isolated to non-isolated leptons in a $E_T$ sideband region. The result in the tagged sample can be calculated in two ways: by applying the method directly to the tagged sample, or by estimating the number of non-$W$ QCD events in the pretag sample and applying an average $b$-tagging rate.

5. RESULTS

We perform a direct search for a resonant mass peak in the reconstructed $W + 2$-jets and dijet invariant mass distributions from the single-tagged and double-tagged events.

Since there is no significant excess of events in the data compared to the predicted background, we set the 95% C.L. excluded region on technicolor production as a function of the technicolor particles mass. A 2-dimensional binned maximum likelihood technique is used on the 2-dimensional distribution of dijet invariant mass vs $Q$-value by constraining the number of background events within the uncertainties, where $Q$-value is defined as $Q = m(\rho_T) - m(\pi_T) - m(W)$. Figure shows the 2-dimensional distribution of data, backgrounds and signal for each tag category.

The final expected and observed excluded region at 95% C.L. are shown in Figure A region of $m(\rho_T) = 180 - 250$GeV are excluded at 95% C.L. based on the Technicolor Straw Man Model, except the region which are near the $W\pi_T$ production threshold with $m(\rho_T) \geq 220$GeV and $m(\pi_T) \geq 125$GeV.
