Abstract

The posttranscriptional regulator RsmA controls the production of plant cell wall degrading enzymes (PCWDE) and cell motility in the Pectobacterium genus of plant pathogens. In this study the physiological role of gene regulation by RsmA is under investigation. Disruption of rsmA gene of the Pectobacterium wasabiae strain, SCC3193 resulted in 3-fold decrease in growth rate and increased virulence. The comparison of mRNA levels of the rsmA mutant and wild-type using a genome-wide microarray showed, that genes responsible for successful infection, i.e. virulence factors, motility, butanediol fermentation, various secretion systems etc. were up-regulated in the rsmA strain. The rsmA strain exhibited a higher propensity to swarm and produce PCWDE compared to the wild-type strain. Virulence experiments in potato tubers demonstrated that in spite of its more efficient tissue maceration, the rsmA strain’s ability to survive within the host is reduced and the infection site is taken over by resident bacteria. Taken together, in the absence of RsmA, cells revert to a constitutively infective phenotype characterized by expression of virulence factors and swarming. We hypothesize that lack of control over these costly energetic processes results in decreased growth rate and fitness. In addition, our findings suggest a relationship between swarming and virulence in plant pathogens.

Introduction

Members of the Pectobacterium genus are plant pathogens responsible for causing soft rot in numerous types of plants, including economically important carrot and potato crops. The main factors of pathogenicity involve bacterial motility and production of plant cell wall degrading enzymes (PCWDE). The latter include pectinases, cellulases, and proteases, and these are produced in large amounts following contact with a host plant [1]. To avoid a counterattack by a host, a pathogen attack must be fast and intense, thereby making it energetically expensive. Therefore, the expression of virulence factors is tightly controlled by environmental factors via a cellular regulatory network. In the genus Pectobacterium, there are three major, partly overlapping regulatory systems (Fig. 1). One involves the repressor protein, KdgR, which suppresses the production of PCWDE without induction by host-related substances [2]. Second pathway involves quorum sensing that suppresses production of virulence factors before high population densities are reached within a plant host [3], [4]. In the third pathway, the flagellar master regulator, FlhDC, promotes the production of both flagella and PCWDE. Thus, in Pectobacterium motility and production of virulence factors are coupled [5], [6]. The effect of quorum sensing on virulence factor production is mediated through the posttranscriptional regulator, RsmA [7]. RsmA binds to a target mRNA to down-regulate its translation and promote its degradation [8], [9].

homologs have widespread regulatory functions in bacteria, including roles in motility [13], central carbon metabolism [14], in E. coli, secondary metabolism, and numerous functions involving interactions between Pseudomonas fluorescens and plant hosts [15–17]. Correspondingly, entries in the protein families database, Pfam, indicate that homologues of CsrA/RsmA are present in a nearly half of bacterial species [18]. In some enterobacterial species, the rsmA gene has been shown to be essential since its knock-out strain is not viable [19], [20]. However, depending on the growth conditions, inactivation of csaA in E. coli has been achieved [21]. Moreover, in Serratia marcescens and Pectobacterium carotovorum, rsmA-defective strains have also been reported [22], [23].

Here, we investigate the global regulatory role of RsmA in Pectobacterium wasabiae SCC3193 (Pw). Both microarray analysis and physiological characterization of the rsmA mutant are reported. Our analysis reveals that RsmA is a key regulator involved in adaptation of Pw for infection/colonization of host plant.

Materials and Methods

Bacterial strains and plasmids

The Pectobacterium wasabiae wild-type strain, SCC3193 (previously identified as Pectobacterium carotovorum subsp. carotovorum), and its rsmB-defective mutant have been described previously [24–26]. To construct a Pw rsmA-deficient strain, the rsmA sequence from the genomic DNA of SCC3193 was PCR amplified using primers, RAP17 (5’-ATCTTTCAAGGAAGAAATGC-3’) and RAP18 (5’-CCGGAACCCGAGAGCGATTG-3’), and was subsequently cloned into the pUTmini-Tn5Km vector [27]. In the resulting construct, the rsmA gene was inactivated by cloning the cat gene (Cm,) into the BsEII restriction site. This vector construct was then used as a template to amplify rsmA::Cm fragment (using primers RAP17 and RAP18), which was used to generate a rsmA-defective strain according to the method described by Datsenko and Wanner [28]. The resulting strain contained a chromosomal insertion of the chloramphenicol resistance gene 64 nucleotides downstream of the translational start codon of the rsmA coding sequence. PCR-amplified rsmA (using primers RAP17 and RAP18) and rsmB (using primers rsmB2 (5’-AATCATTATTATGTTTAAG-3’) and AE16AEPA (5’-AGCCAGATCTGAGGTATG-3’) and PROM8 (5’-AAGGTACCCCAGTGGCTGTT-3’). The amplified fragment was cloned in frame with the gusA reporter gene in the low-copy vector, pMW119 (Eurogentec).

Virulence assay in tobacco seedlings

Virulence of the Pw wild-type and mutant strains was tested in 3-to-4-week-old tobacco seedlings (Nicotiana tabacum var. Samsun), grown in 24-well tissue culture plates in Murashige-Skoog medium. Seedlings were surface inoculated by pipetting bacterial solution (107 bacterial cells) onto plants without wounding. The inoculated plants were incubated in a plant growth chamber with high humidity. The development of disease symptoms (i.e., tissue maceration) was monitored for 24–72 h after inoculation.

Gene transcription level profiling

Total RNA was isolated from wild-type and rsmA-defective strains grown on M9 minimal plates containing 10% potato tuber extract using Trizol reagent according to the manufacturer’s protocol (Invitrogen). To eliminate any traces of genomic DNA prior to RNA amplification, an additional DNase I treatment was performed according to the supplier’s protocol (Fermentas).

Extracted RNA from samples was checked for sufficient purity using NanoDrop and an Agilent bioanalyzer (containing a RNA Nano 6000 chip) prior to being treated with a MICROBExpress kit (Ambion) to remove 16S and 23S rRNAs. According to the manufacturer, this process significantly increases the sensitivity of downstream applications such as microarrays. Purified mRNA from each sample was checked for sufficiently low rRNA contamination using a bioanalyzer, and then was treated with a MessageAmpTM II-Bacteria RNA Amplification kit (Applied Biosystems) according to the manufacturer’s instructions. This kit was supplemented with 5-(3-aminomethyl)-UTP, ultimately producing antisense RNAs (aRNAs) which were subsequently labeled with fluorescent dyes (based on binding to the aminomethyl-UTP). The three different dyes used were: Alexa488 (Invitrogen), Cy3, and HyPer5 (Amersham). aRNA (5 µg) from each biological replicate was dried in a vacuum centrifuge, then resuspended in 7 µl sterile MQ water and 9 µl Na2CO3 buffer (pH 9.3). Fluorescent dye (4 µl) was then added, and a different dye was incubated with each biological replicate. Samples were subsequently incubated at RT in darkness for 1 h, then for an additional 15 min following the addition of 4M hydroxylamine (4.5 µl/sample). Samples were purified using a PureLink PCR purification kit (Invitrogen), then hybridized on an Agilent microarray for 17 h in a G2545 Agilent hybridization oven, according to the manufacturer’s instructions (One-Color Microarray-Based Gene Expression Analysis Low Input Quick Amp Labeling, v6.5). The Agilent 8×15k custom microarray contains 60mer probes covering a total 4571 ORFs.

The microarray slide was scanned using a GenePix 4110AL scanner (Axon Instruments) and analyzed with GenePix pro 6.1. Data were also analyzed using Bioconductor, a limma software package for the R programming language. Normalization was achieved using quantile normalization, empirical Bayesian vari-
ance shrinkage was used for statistical analysis, and data were
combined from all probes for each gene. A false discovery rate (fdr)
value of 0.05 was used as the cut-off for significance in statistical
analyses.

Extracellular enzyme assays

For the quantitative analysis of extracellular pectate lyases,
polygalacturonase, and proteases, strains were grown in M9
minimal media [29] supplemented with appropriate trace
elements [30] and a carbon source (0.2% glucose or 0.2%
polygalacturonic acid). Extracellular enzyme activities were
measured in cell-free supernatant samples according to previously
published protocols [31], [32]. To perform semi-quantitative
agarose plate assays of extracellular protease and polygalacturo-
nase production, cells were spotted on respective indicator plates
described by Chatterjee and coworkers [23], with the exception
that a milk-containing agar plate additionally contained 0.05%
polygalacturonic acid as an inducer for proteases. Plates were
incubated at 30°C and observed 24 and 72 h after incubation (for
pectinolytic enzymes and proteases, respectively). Enzyme activity
was evaluated according to the size of the halo around each
colony, which is proportional to the amount of secreted enzyme.

Analysis of prtW expression

Strains containing the prtW::gusA translational fusion
(pLATSprtW) were grown in M9 minimal medium supplemented
with 10% celery extract. GusA activity was measured in the
exponential and early stationary phases of growth using 4-
methylumbelliferyl β-d-glucuronide (DUCHEFA Biochem) as a
substrate, according to Andresen et al. [5].

Identification of extracellular proteins

Cell-free supernatants were collected from cultures grown in
minimal glucose and PGA medium, and these samples were
concentrated 20 times by acetone precipitation. Proteins were
separated by SDS-PAGE (11%) and protein bands were visualized
using Comassie Blue R-250 staining. Proteins were cleaved
with trypsin and LysC proteases, analyzed by mass spectrometry (LTQ
Orbitrap), and identified with searches against the SwissProt
database using Mascot software.

Motility tests

The swimming phenotype of Pw strains was evaluated by
stabbing fresh cultures with sterile toothpicks and then inserting
the toothpicks into 0.25% agar plates containing M9 minimal media
with trace elements and 0.4% polygalacturonic acid as a
carbon source.

Swarming motility was assayed by spotting each strain onto
minimal plates containing 0.4% agar and 10% potato tuber
extract.

Both swimming and swarming motility phenotypes for each
strain were evaluated visually by observing the migration of cells
away from the inoculation site.

Flagella staining

Macerated potato tuber tissues (~0.2 g each) were gently
soaked in 1 ml distilled water, cut into small pieces without any
agitation, and placed in tubes. Samples were left to stand for
~15 min until the pieces of potato precipitated. The upper
bacterial suspension was then removed (~500 µl) to a new
Eppendorf tube and centrifuged for 3 min at 100 g. The upper
aerated phase was removed and the cells were gently resuspended
in an appropriate volume of distilled water. This bacterial solution
(10 µl) was immediately pipetted onto a microscope slide and left to
dry very slowly under a cover before staining of flagella was
performed according to West et al [33].

Glycolic and lactic acid production

The glycolic content of each strain was evaluated on solid
Kornberg medium (1.1% K2HPO4, 0.85% KH2PO4, 0.6% yeast
extract, 1% glucose) agar plates. Strains were grown on these
plates for 24 h at 30°C then exposed to iodine vapor for 10 min to
assess glycogen accumulation.

Characteization of butanediol fermentation products

Potato tubers were inoculated with 5 × 106 bacterial cells
suspended in 10 mM MgSO4. After 24 and 48 h at 30°C, tubers
were cut in half and macerated tissue present was removed from
the inoculation site into Eppendorf tubes. Following centrifugation
at 15 700 g for 10 min, supernatants were analyzed using the
Voges-Proskauer test [34]. A red color indicated the presence of
acetoacetin, and its accumulation was quantified at OD530 nm.

Virulence assay in potato tubers

Surface-sterilized potato tubers (cv. Ants) were stabbed with a
sterile pipette tip and solutions of wild-type or rsmA- cells (5 × 108)
in 10 mM MgSO4 were transferred into the wound. Negative
controls were inoculated with sterile 10 mM MgSO4. Tubs were
kept at 30°C under plastic to maintain moist conditions. Virulence
was estimated by weighing the rotted tissue present in tubers 20
and 40 h after inoculation.

To estimate the number of bacteria present in the infection sites,
a 2.5 g of tissue surrounding the infection site was resected,
weighed, and homogenized in sterile 0.9% NaCl. Dilutions for
CFU counting were plated on LB agar plates, except for rsmA- cells
which were plated on LB plates containing Cm. Colonies
were counted after plates were incubated for 24 or 72 h at 30°C
for wild-type and rsmA- strains, respectively. To distinguish
between Pw and other species of bacteria inhabiting the tubers,
colonies were tested for the production of PCWDE on indicator
plates.

Results

Construction of the rsmA knockout

To generate a knockout mutant of rsmA in the Pw, a Cm
resistant marker was inserted into the rsmA gene 64 nucleotides
downstream of the translational start codon. The resulting rsmA- strain
was observed to have a slower growth rate than the wild-
type Pw, independent of the medium used. To examine the
physiological parameters of rsmA- growth, liquid minimal medium
containing a sole carbon source, 0.2% glucose or 0.2% poly-
galacturonic acid (PGA) was used. PGA mimics a plant
component for induction of PCWDE. The rsmA- was compared to
both wild-type and rsmB- strains. The generation times for
wild-type, rsmB-, and rsmA- strains in 0.2% glucose were 73, 75,
and 240 min, respectively. In 0.2% PGA, the generation times
were 85, 88, and 230 min, respectively. Accordingly, the rsmA-
strain grows 2.5–3 times more slowly than wild-type or rsmB-
strains.

Next, the virulence of the rsmA- mutant was compared with wild-type and rsmB- strains in 3-to-4-week-old tobacco seedlings
(Fig. S1). Three days post inoculation, there were no disease
symptoms observed in plants infected with the rsmB- mutant.
In contrast, 63% of rsmA- infected plants, and 22% of plants infected
with the wild-type strain, were completely macerated. Based on
these results, the *rsmA*− strain appears to have increased virulence despite exhibiting a reduced growth rate.

**RNA microarray analysis**

To elucidate the mechanism(s) mediating the increase in tissue maceration associated with the *rsmA* mutant, global transcript level analysis was performed for *Pw*. For these studies, a DNA microarray containing 4571 open reading frames (ORFs) of *Pw* was used. Total RNAs were extracted from wild-type *Pw* and the *rsmA*− strain that were grown on 1.5% agar containing solid minimal medium supplemented with 10% potato extract to mimic *in planta* growth conditions. Based on the differences in growth, samples were collected from the *rsmA*− strain 40 and 48 h post inoculation, while wild-type samples were collected after 24 h. RNA pools for these samples were then hybridized to microarrays and the gene transcript level profiles obtained were compared.

Although differences in the mRNA expression levels between wild-type and *rsmA*− strains were not large, 39% of the ORFs analyzed (i.e., 1800 ORFs) showed statistically significant differences between the two strains (p≤0.05). In addition, the number of ORFs with differences between the *rsmA*− strain and wild-type was considerably higher at the 40 h time point than at the 48 h time point (1631 vs. 565, respectively). The number of ORFs exhibiting differences at both time points was 396. In all cases, approximately half of the differentially expressed ORFs were transcribed at higher levels in the *rsmA*− strain than in the wild-type strain (available in NCBI GEO database, series accession: GSE40333; ID: 200040333).

To analyze the universal role of *rsmA* in *Pectobacteria*, the results of the *Pw* microarray were compared with previously reported results from a microarray analyzing mRNA level profiles of wild-type *P. atrosepticum (Pa)* versus an *expI* strain [3]. The inactivation of *expI* leads to increase in RsmA level (Fig. 1) [7]. Although the conditions in which the cells were grown prior to RNA extraction were different (plates containing potato extract for *Pw* vs. potato plant for *Pa*), there were several genes with mRNA levels showing trends in opposite direction in the two experiments, as would be expected for the opposite *rsmA* expression levels (Fig. 2). In addition to known virulence factors, PCWDE and flagella, that were up regulated in *rsmA*− strain and down regulated in *expI* strain, there were several groups of genes showing large effects: type VI secretion system, the phosphonate cluster, glycogen metabolism, citrate uptake and degradation, butanediol fermentation and TCA cycle, whereas the genes for cell division, peptidoglycan synthesis and lipopolysaccharide synthesis were down regulated in *rsmA*− strain and up regulated in *expI* strain (Fig. 2).

In subsequent experiments, the contribution of RsmA to infection/virulence-linked physiological traits and the general energetic state of the cell are further examined.

**Plant cell wall degrading enzymes (PCWDE)**

Levels of mRNA for PCWDE and genes coding for export systems for PCWDE, were found to be at higher levels in the *rsmA* defective strain than in the wild-type strain. To better understand these microarray data, the *rsmA*− strain and the wild-type strain were grown in liquid minimal medium containing either 0.2% glucose or 0.2% PGA as the sole carbon source. The activity of three PCWDE was then assayed throughout their growth curves. These included polygalacturonase (Peh), pectate lyases (Pel), and protease (Prt) (Fig. 3). In glucose medium, the levels of Peh activity were 5–7 times higher in the *rsmA*− strain than in the wild-type strain. Moreover, in *rsmA* mutants, levels of Peh activity were similar for glucose and PGA samples, while wild-type cells exhibited a clear induction of Peh activity by the plant component PGA. In contrast, levels of Peh activity in the *rsmB* knockout were not considerable.

Pel activity was also higher in the *rsmA*− strain compared to the wild-type strain, and induction by PGA was minimal. For the *rsmB*− strain, Pel activity was only detectable in cells grown with PGA (Fig. 3).

It was also observed that Pel and Peh production started earlier in the *rsmA*− strain compared with the wild-type strain (data not shown). A lack of quorum sensing in the *rsmA*− strain is a probable explanation for this phenomenon. Transcription of *rsmA* in wild-type *Pw* is under the negative control of the quorum sensing signal, homoserine lactone (HSL) [7]. ExpR1/R2 proteins activate the transcription of *rsmA* until HSL accumulates, and then HSL binds ExpR1/R2 to release the complex from the promoter region of *rsmA* (Fig. 1) [35]. Thus, in the late exponential phase of wild-type *Pw*, the accumulated HSL removes activation of RsmA synthesis that causes induction of Peh and Pel. In the absence of RsmA this regulatory cascade is interrupted and the knockout strain is constantly in state similar to the wild-type strain in the late exponential phase.

Based on the microarray data collected, it was hypothesized that the protease activity of the *rsmA*− strain would be high. However, although the protease activity of cells grown in glucose was slightly higher in the *rsmA*− strain versus the wild-type strain, *rsmA*− cells exhibited ~5-fold lower levels of protease activity in PGA liquid culture than wild-type cells. Moreover, no detectable protease activity was present in *rsmB*− cells, indicating that the Rsm system controls protease production. To clarify this apparent discrepancy, we added *rsmA* gene or *rsmB* gene on plasmid to wild type cells. Consistent with microarray data, over-expression of RsmA suppresses the protease production while the small RNA RsmB enhances the protease production in wild-type cells (Figs. 3, 4).

To further verify the mRNA level profiling data obtained, the *prtW* regulatory region was fused to the GusA coding region to detect *prtW* expression in wild-type, *rsmA*−, and *rsmB*− strains. As shown in Figure S2, the expression of GusA was higher in the *rsmA*− strain than in the wild-type strain, while in the *rsmB*− strain it was lower than in the wild-type strain. These results are consistent with the microarray data, and suggest that expression of *prtW* in the *rsmA*− strain was down-regulated at the level of protein stability, protein export, or enzymatic activity.

**Extracellular proteins**

Although high levels of extracellular Peh and Pel activity were detected in the *rsmA*− strain, it was not clear whether higher levels of extracellular protein expression by the *rsmA*− strain were limited to PCWDE, or whether a general increase in protein export was involved. To distinguish between these possibilities, culture supernatants of wild-type and *rsmA*− strains were concentrated and then separated by SDS-PAGE. (Fig. 3E). Using mass spectrometry, the most abundant proteins detected in the *rsmA*− growth medium were PehA, Pel1, Pel2, Pel3, and CelV, along with traces of flagellin, Fic, and translation elongation factor, EF-Tu. These results indicate that the increased extracellular protein production associated with the *rsmA*− strain is specific to PCWDE.

**Motility**

According to the array data, majority of the genes that encode flagella proteins are up-regulated in the *rsmA*− strain, in accordance with previous studies of the Rsm system [36]. It has also been shown in several bacteria, including *Pectobacteria*, that RsmA/CsrA represses motility [20], [22], [36], [37]. The increased synthesis of flagella proteins and the energy consumption
required for active flagella is a huge energetic commitment for a cell. To determine whether increased production of flagella in the rsmA strain contributes to the slower growth rate observed, studies of motility, both swimming and swarming, were conducted for rsmA, rsmB, and wild-type strains (Fig. 5). While the rsmB and wild-type strains exhibited similar rates of swimming, rsmA cells were unable to spread in the 0.25% agar used for the assay. Moreover, this inability to swim was observed in PGA, glucose and glycerol media but not when 20 amino acids at final concentration of 100 μg/ml each were added to these media (data not shown). In addition, the swimming activity of the three strains was subsequently examined in liquid media using a phase contrast

![Figure 2. In Pectobacteria rsmA expression level affects transcriptome.](image)

A global mRNA profile of the rsmA of Pw was compared with its parental strain. The results were compared with a previous study of the expI strain of Pa [3]. In the expI strain the RsmA level is increased [7]. The genes included in the figure are those which passed two criteria: firstly, the expression level changes were in the opposite direction in response to rsmA inactivation as compared to rsmA up-regulation (expI strain); secondly, the genes have been associated with virulence. The scale bar (top of figure) represents the fold change in mRNA levels between the wild-type and the rsmA Pw strain, with positive values representing up-regulation and negative values representing down-regulation in the rsmA− strain.

...results suggest that during the lag period in wild-type cells, both... 

**Swarming motility generally requires an energy-rich, solid medium. However, the conditions specific for inducing swarming can vary for different bacteria [38].** In this study, swarming motility was assayed on 0.4% agar plates with different rich media containing celery extract or potato tuber extract to simulate plant induction. Swarming was only observed on plates containing 10% potato tuber extract. *P. wasabiae* cells were observed to swarm rather quickly across the semi-solid surface, covering it with a hardly visible layer of cells (Fig. 5). In contrast, wild-type cells started to swarm on the third day of incubation (data not shown), while *rsmB* cells remained at the site of inoculation. The increased swarming activity observed for the *rsmA* strain is in accordance with the increased production of flagella detected in the microarray data.

**Figure 4. Plasmid expression of rsmA or rsmB can complement the corresponding knock-out mutants.** A. The production of protease (Prt) was assayed using a specific, semi-quantitative indicator plate, where the halo around the inoculation site was proportional to the amount of enzyme produced. Exogenous expression of *rsmA* and *rsmB* (prsmA and prsmB, respectively) was achieved, with pBSK being the vector control. B. To assess glycogen accumulation, cells were grown on Kornberg’s medium then exposed to iodine vapors. Darker staining represents higher levels of glycogen. Assays were performed at least three times, and no significant variations were observed. doi:10.1371/journal.pone.0054248.g004

**Figure 5. RsmA affects the swimming and swarming motility of *Pw*.** A. The swimming ability of wild-type, *rsm* mutants (*rsmA* and *rsmB*), and the respective overexpression strains (wt + prsmA and wt + prsmB) were evaluated based on the migration speed of these cells in 0.25% soft agar plates containing polygalacturonic acid. Cells were imaged 48 h after inoculation. B. The swarming ability of the wild-type, *rsm* mutants (*rsmA* and *rsmB*), and the respective overexpression strains (wt + prsmA and wt + prsmB) were evaluated. The ability of the cells to migrate on the surface of the medium, away from the site of inoculation was examined on 0.4% agar plates containing 10% potato extract. Plates were imaged 24 h after inoculation. Swarming of the wild-type strain was not observed until 72 h after inoculation (not shown). All images are representative of five different experiments performed, and no significant variability was observed between the experiments. doi:10.1371/journal.pone.0054248.g005
TCA cycle, glyoxylate shunt, and glycogen metabolism

The reduced growth rate of $rsmA^2$ mutants may be linked to a low energy state for these cells that is caused by increased production of virulence factors. The mRNA levels of genes involved in the glyoxylate shunt were found to be down-regulated, and genes for the TCA cycle were up-regulated, in the microarray data obtained (Figs. 2, 7).

The microarray analysis performed detected the up-regulation of genes for glycogen synthesis, including $glgA$, $glgC$, and $glgB$, as well as a gene for glycogen degradation, $glgX$, in the $rsmA^2$ strain (Fig. 2). To confirm these results, glycogen accumulation on solid Kornberg medium was assayed with iodine vapor staining. As shown in Figure 4, the $rsmA^2$ strain had slightly decreased glycogen levels.

In E. coli, the RsmA homologue, CsrA is a protein originally described as a regulator of carbon metabolism [12]. In csrA$^2$ knock-out, glycogen synthesis is favored and excess glycogen accumulation impairs viability [21]. Thus, in contrast with the E. coli csrA$^2$ mutant, the Pw $rsmA^2$ mutant consumes resources rather than saves them, and the increased consumption of glycogen may be linked to the energy deficiency associated with the $rsmA^2$ mutant.

Fermentation

Under the low oxygen conditions of internal plant tissues, plant-associated Enterobacteriaceae commonly ferment sugars through the 2,3-butanediol pathway. In the $rsmA^2$ mutant, the genes responsible for 2,3-butanediol production (i.e., budA, budB, and budC), were found to be slightly up-regulated in the microarray data collected (Fig. 2). To confirm these results, levels of acetoin, a predecessor of 2,3-butanediol, were detected in macerated potato tuber tissue infected with wild type or $rsmA^2$ mutant cells. As shown in Figure 8, levels of 2,3-butanediol fermentation were higher in the $rsmA^2$ strain, which accounts for the higher pH of macerated potato tuber tissue collected from the $rsmA^2$ strain compared to tissue infected with the wild-type strain (pH 6 vs. pH 5.5, respectively).

The alkalization of growth media by 2,3-butanediol promotes the growth of bacteria that are unable to cope with acidic conditions in the plant. Therefore, the higher pH of potato tissue

**Figure 6.** Pw cells change their shape and flagellation depending on their growth environment. Wild-type (wt) and $rsmA^-$ strains grown in different media, as indicated, had their flagella stained according to West et al. [33]. Representative images of cells grown in the liquid medium (0.2% PGA liquid broth), swarming plate (0.4% agar containing 10% potato extract) and potato tuber are shown. The samples from potato tubers were collected 20 h after inoculation, all the other samples 24 h after inoculation. On the swarming plate the wild-type cells became long and hyperflagellated after 72 h of inoculation (not shown).

**Figure 7.** The role of RsmA in regulating the tricarboxylic acid (TCA) cycle and glyoxylate bypass. Blue arrows indicate reactions catalysed by the enzymes corresponding to genes up-regulated in the $rsmA$ strain according to microarray data. Red arrows indicate reactions catalysed by the enzymes corresponding to genes down-regulated in the $rsmA$ strain. icd–isocitrate dehydrogenase; sucA–2-ketoglutarate dehydrogenase; sucCD–succinyl CoA synthetase; sdhACDB–succinate dehydrogenase; fumA–fumarase; mdh–malate dehydrogenase; citrate–citrate synthase; acn–aconitase; aceA–isocitratelyase; aceB–malate synthase.

The Role of RsmA in Pectobacterium wasabiae

PLOS ONE | www.plosone.org 8 January 2013 | Volume 8 | Issue 1 | e54248
Figure 8. RsmA regulates butanediol fermentation in potato tubers. A. Potato tubers infected with wild-type (wt) or rsmA strains were assayed for activity of the butanediol fermentation pathway. Specifically, production of acetoin (an intermediate in the butanediol fermentation pathway) was detected spectrophotometrically (at 530 nm) using the Voges-Proskauer method 24 h after inoculation [34]. The experiment was performed in triplicate and error bars indicate standard deviation values. The colorimetric reaction associated with each result is shown below the graph. B. The butanediol fermentation pathway in Pectobacteria. The reactions are catalysed by enzymes coded by budB (acetolactate synthase), budA (α-acetolactate decarboxylase), and budC (acetoinreductase).

Figure 9. The RsmA mutant is able to grow aerobically on citric acid. Wild-type (wt), rsmA, and rsmB strains were tested for their ability to grow aerobically in minimal medium containing 0.2% citric acid as the sole carbon source. The absorbance of cultures at 580 nm was recorded up to 27 h post inoculation. Experiments were performed in triplicate.
doi:10.1371/journal.pone.0054248.g009

Since the generation time of the $rsmA^-$ strain is 3–4 times slower than that of the wild-type strain, the ability of the $rsmA^-$ strain to multiply in potato tubers was studied. For these studies, dilutions of macerated tissue generated from the incubation of potato tubers with either the wild-type or the $rsmA^-$ strain were plated on LB. After 20 h, in experiments with both strains the total bacterial numbers reached $10^9$ CFU per gram of macerated tissue (Fig. 10B). The plates with the wild-type strain contained uniform colonies with growth rate and PCWDE production identical to the original Pw strain. However, the LB plates inoculated with the dilutions of the $rsmA^-$ macerated tissue contained colonies with variable colony morphologies and growth rates. This prompted us to plate the $rsmA^-$ macerated tissue in parallel to the selective LB+Cm plates. The number of cells growing in the presence of Cm was 2 magnitudes lower than the total colony count. Therefore, it appears that the $rsmA^-$ strain represents only a minority of the bacteria present in macerated tissue. Moreover, the bacterial count in control tubers, inoculated with the buffer not generating macerated tissue was quite high, revealing the presence of resident microflora in the tubers (Fig. 10B). After 40 h of incubation the $rsmA^-$ cells were almost completely disappeared and the infection site was taken over by the indigenous bacteria although the amount of macerated tissue was high. Taken together, these results demonstrate that although the $rsmA^-$ mutant is able to produce more virulence factors and causes more damage to plant tissue, its ability to cope with the resident microflora or other conditions found in the potato tubers is reduced compared to the wild-type strain.

The effects of $rsmA^-$ mutation on cell and flagella morphology were also examined in macerated tissues. At both time points, 20 h and 40 h, wild-type cells were observed to be elongated and hyperflagellated. However, for the $rsmA^-$ cells at the 20 h time point, cells were extremely long, filamentous, thin, and hyperflagellated, similar to the phenotype observed for $rsmA^-$ cells on swarming plates. After 40 h, it was difficult to detect $rsmA^-$ cells due to the presence of numerous types of bacteria with various cell shapes.

In conclusion, the similarity of wild-type cells swarming on agar plates containing potato extract and cells isolated from potato tubers following infection suggests that the physiological state of...
The Role of RsmA in *Pectobacterium wasabiae*

**Figure 10. The virulence and survival of wild-type and rsmA" strains over the course of potato tuber infections.** Potato tubers (n = 30) inoculated with 5 x 10^6 CFU of wild-type (wt) or rsmA" cells were placed in plastic boxes and incubated at 30°C. A. At 20 h and 40 h post inoculation, macerated tissue was removed from the inoculation site and weighed. Error bars indicate standard deviation values. B. The number of bacteria residing in the infection sites infected with wt, rsmA" cells or buffer was determined by plating dilution series (green, blue and yellow). The number of rsmA" bacteria present in infection sites was determined using Cm-containing plates to avoid overgrowth by other bacteria inhabiting the infection sites (red). Circles and triangles represent data from the 20 h and 40 h time points assayed, respectively. Horizontal lines represent the median values.

doi:10.1371/journal.pone.0054248.g010

Potato-infesting bacteria is similar to that of the swarming state. Moreover, the increase in swarming activity observed for the rsmA" mutant suggests that RsmA is involved in the switch to a swarming phenotype.

**Discussion**

The microarray data collected in this study reveal global changes in physiology and metabolism occur in *Pw* with the loss of rsmA. Some of these changes involve the synthesis of PCWDE and other virulence factors, flagella synthesis and motility, the switch from glycogen production to glycogen consumption, increased citrate uptake, butanediol fermentation, and regulation of the TCA cycle to maximum energy production. These physiological processes are required for adaptation at the site of bacterial invasion in response to a host plant. In addition, when microarray data from deletion of rsmA were compared with rsmA overexpression in *Pa* (i.e., the expI" mutant) [3], several gene clusters strongly repressed by RsmA were identified. In particular, type VI secretion and phosphonate metabolism. The expression of these gene clusters has been shown to be promoted by plant extracts [47], although their functions in relation to virulence are unknown. We identified many additional genes that are oppositely regulated in response to rsmA deletion and overexpression. As these genes have no obvious role in virulence, these were not analyzed in the current study and await for future investigations.

The slow growth phenotype of rsmA" cells could be considered similar to those of strains expressing large quantities of non-functional, non-toxic proteins from multi-copy plasmids. In the case of rsmA" cells, the “gratuitous” proteins are the highly produced PCWDEs, and these are not essential for bacterial growth. It has been shown that the accumulation of excessive proteins is accompanied by a progressive decrease in cell growth rates [48]. High growth rates require the continuous production of housekeeping proteins. Due to limited quantities of free RNA polymerase and ribosomes in the cell, the expression of excessive proteins thereby leads to a decrease in growth rate [49].

In the rsmA knock out mRNA levels of genes involved in the glyoxylate shunt were found to be down-regulated, and genes for the TCA cycle were up-regulated (Figs. 2, 7). The glyoxylate bypass can provide anabolic intermediates; the TCA cycle is more efficient at providing energy. The glyoxylate shunt enzyme, isocitrate lyase (AceA) competes with the TCA cycle enzyme, isocitrate dehydrogenase (the product of icd), for isocitrate. While isocitrate dehydrogenase has a much higher affinity for isocitrate, it is inactivated by phosphorylation when ATP concentrations are high and the cell needs precursors for biosynthesis [50]. Inhibition of isocitrate dehydrogenase then slows the TCA cycle and forces isocitrate through the bypass. When metabolic intermediates and AMP/ADP accumulate, isocitrate dehydrogenase is then dephosphorylated to function in the TCA cycle [50]. In the rsmA" mutant, increased mRNA levels of genes involved in TCA cycle might be a response to the limited energy resources of these cells. However, whether the up-regulation of proteins in the TCA cycle and the down-regulation of proteins that are part of the glyoxylate shunt is a consequence of the higher energy demand of the rsmA" strain, or is the direct result of gene regulation by RsmA, remains unsolved.

Both wild-type and rsmA" *Pw* cells exhibited a swarming phenotype in potato tubers. In animal pathogens such as *Proteus mirabilis*, *Salmonella typhimurium*, *Serratia marcescens*, *Pseudomonas aeruginosa*, and *Bacillus cereus*, the swarming process is coupled with the invasion of new host cells and virulence factor synthesis [51–54]. Furthermore, transcriptome studies of these bacteria have indicated that profound differences exist between swimmer and swarmer cells [51]. For example, morphological changes of swarmer cells include an increase in the number of flagella and cell elongation. Swarmer cell differentiation results in substantial alterations in metabolism and environmental survival strategies. Regarding the latter, these changes indicate that swarming represents a complex lifestyle adaptation. It has also been demonstrated in *Salmonella* and *E. coli* that a full TCA cycle is needed for swarming motility, a behavior that consumes a lot of energy [51],[55]. Similarly, up-regulation of the TCA cycle in the
*Pw* rsm*A* strain would be predicted to be needed for up-regulation of virulence factor synthesis.

It is commonly believed that swarming cells suppress cell division, and that cell elongation is either a requirement for, or an indicator of, swarming motility. Regarding the filamentous cell shape of *Pw* swarming cells, there are three possible explanations. First, due to the energy required for cells to undergo swarming, cell division could be inhibited, thereby resulting in a filamentous cell shape. Secondly, stress induced by an antibiotic-like compound could be a factor. For example, swarming stimuli are poorly understood. However, they are hypothesized to be induced by environmental signals [56]. In *Pw*, elongated cell shapes and hyperflagellation are promoted by a host. In this study, potato tubers or potato tuber extract were used to represent a host. If certain plant components act as an antibiotic, cell filamentation could be induced. Moreover, in potato tubers, the more susceptible *rsm*A strain was observed to undergo cell death. Thirdly, it is possible that the filamentous cell shape is induced by a potato tuber component which does not cause stress, but rather improves movement in the host.

The most probable reason for the low cell number observed for the *rsm*A strain in potato tubers is unregulated virulence factor synthesis. For example, once a pathogen penetrates a plant cellulose-based cell wall, the pathogen is exposed to plant extracellular surface receptors that recognize pathogen-associated molecular patterns (PAMP) such as bacterial flagellin and EF-Tu [57],[58]. This recognition triggers immunity, which usually halts an infection before a microbe can establish itself in the plant [59],[60]. Therefore, during infection, pathogens actively suppress a plant’s PAMP-triggered defenses [61]. However, plants respond to cell wall damage by activating a variety of defenses [62]. In the *rsm*A strain, the Rsm system is compromised, thereby disrupting induction by quorum sensing and several other regulatory pathways. As a result, deregulated synthesis of PCWDE, flagellin, and other virulence factors occurs. Production of these proteins occurs in the *rsm*A mutant at higher level than in wild-type and may start before the bacteria have reached the critical cell concentration for attacking the plant. Flagellin, EF-Tu, acetoin, butanediol and a damaged cell wall can trigger plant defense responses [43],[44],[57],[58], which a single bacterial cell, although well equipped, cannot resist.

When studying bacteria numbers in infected potato tubers, it was found that despite surface-sterilization with hypochlorite acid prior to inoculation, the resident bacterial community of potato tubers can survive in considerable numbers. This may be due to fissures in the potato peel or bacteria present within the potato. In *rsm*A generated lesions, the number of bacteria present was particularly high, and included a variety of colony structures and sizes. This may be due to increased expression of PCWDE in the *rsm*A strain that could lead to the release of plant components at high levels. However, bacteria intrinsic to the potatoes used for inoculation were also present for the wild-type experiments, indicating that the wild-type *Pw* strain was able to efficiently out-compete these organisms. We hypothesize that the maceration of potato tubers is achieved by a diverse population of bacteria. For example, *Pw* cannot degrade starch, which is the main carbohydrate present in potato tubers. Degradation of the plant cell wall by PCWDE of *Pw* could expose the starch present to other bacteria.

In conclusion, plant invasion is a hazardous and energy consuming process for bacteria, and accordingly, has to be tightly regulated. Therefore, the unregulated production of virulence factors at high levels in the *rsm*A strain is energetically costly, and can reduce the ability of *Pw* to invade a plant and compete with the natural bacterial community of the host. Moreover, in *Pw*, an attack of a plant and the induction of virulence factors are accompanied by a swarming phenotype.
