Quantum chromodynamics (QCD) predicts that the strong force between quarks and gluons becomes weaker when probed at high momentum transfers, corresponding to small distances. This property, referred to as asymptotic freedom, is derived from the renormalization group equation (RGE) \[\eqref{RGE}\]. The RGE does not predict the value of the strong coupling \(\alpha_s\), but it describes the dependence of \(\alpha_s\) on the renormalization scale \(\mu_R\), and therefore on the momentum transfer. Tests of perturbative QCD (pQCD) and the property of asymptotic freedom can be divided into tests of the validity of the RGE and determinations of the value of \(\alpha_s\). By convention, \(\alpha_s\) values extracted from data at different momentum transfers are evolved to the common scale \(\mu_R = M_Z\) to allow comparisons between experiments. The current world average value is \(\alpha_s(M_Z) = 0.1184 \pm 0.0007\) \[4\]. The validity of the RGE is tested by studying the dependence of \(\alpha_s\) on the momentum transfer. At present, the RGE predictions have been tested in deep-inelastic \(e^+ e^-\) annihilation, where \(\alpha_s\) results have been obtained for momentum transfers up to 208 GeV \[4\]. Attempts to extract \(\alpha_s\) at higher momentum transfers have been carried out using inclusive jet cross section data in hadron-hadron collisions \[4, 6\]. These analysis methods require parton distribution functions (PDFs) of the proton at large scales as input. Since the main constraints on PDFs come from data at lower scales, the knowledge of PDFs at large scales is mainly based on the evolution according to the Dokshitzer-Gribov-Lipatov-Altarelli-

We present a measurement of the average value of a new observable at hadron colliders that is sensitive to QCD dynamics and to the strong coupling constant, while being only weakly sensitive to parton distribution functions. The observable measures the angular correlations of jets and is defined as the number of neighboring jets above a given transverse momentum threshold which accompany a given jet within a given distance \(\Delta R\) in the plane of rapidity and azimuthal angle. The ensemble average over all jets in an inclusive jet sample is measured and the results are presented as a function of transverse momentum of the inclusive jets, in different regions of \(\Delta R\) and for different transverse momentum requirements for the neighboring jets. The measurement is based on a data set corresponding to an integrated luminosity of 0.7 fb\(^{-1}\) collected with the D0 detector at the Fermilab Tevatron Collider in \(p\bar{p}\) collisions at \(\sqrt{s} = 1.96\) TeV. The results are well described by a perturbative QCD calculation in next-to-leading order in the strong coupling constant, corrected for non-perturbative effects. From these results, we extract the strong coupling and test the QCD predictions for its running over a range of momentum transfers of 50–400 GeV.

\[\eqref{deltaR}\]
Parisi (DGLAP) evolution equations which use $\alpha_s$ and the RGE as input. The $\alpha_s$ results from inclusive jet cross section data at high momentum transfers can therefore not be regarded as tests of the RGE, since they are obtained assuming its validity.

In this Letter a new observable for hadron-hadron collisions is introduced and its average value is measured. It is related to the angular correlations of jets. In pQCD, this quantity is computed as a ratio of jet cross sections, which is proportional to $\alpha_s$. Since PDF dependencies largely cancel in the ratio, the extracted $\alpha_s$ results are almost independent of initial assumptions on the RGE. Values of $\alpha_s$ are extracted for momentum transfers between 50 and 400 GeV. These provide the first test of the RGE at momentum transfers above 208 GeV.

The analysis presented in this Letter studies the properties of multi-jet production based on an inclusive jet sample in $pp$ collisions at $\sqrt{s} = 1.96$ TeV. While pQCD predictions for any cross section at a hadron collider depend on the PDFs, quantities with significantly reduced PDF sensitivity can be constructed. One class of such quantities is ratios of three-jet and dijet cross sections. Based on such ratios, one can exploit the high energy reach at hadron colliders to determine $\alpha_s$ and to test the predictions of the RGE at previously unexplored momentum scales. A new observable is introduced, which probes the angular correlations of jets in the plane of rapidity $y$ and azimuthal angle $\phi$. This observable measures the number of neighboring jets that accompany a given jet with transverse momentum ($p_T$) with respect to the beam axis. The measured quantity $R_{3j}$ is the ensemble average over all jets in an inclusive jet sample of this observable. The inclusive jet sample consists of all jets in a given data set, and these jets are hereafter referred to as “inclusive jets”. The measured quantity is given by

$$R_{\Delta R}(p_T, \Delta R, p_{T_{\text{min}}}) = \frac{\sum_{i=1}^{N_{\text{jet}}(p_T)} N_{\text{nbr}}^{(i)}(\Delta R, p_{T_{\text{min}}})}{N_{\text{jet}}(p_T)}$$

(1)

where $N_{\text{jet}}(p_T)$ is the number of inclusive jets in a given inclusive jet $p_T$ bin, and $N_{\text{nbr}}^{(i)}(\Delta R, p_{T_{\text{min}}})$ is the number of neighboring jets with transverse momenta greater than $p_{T_{\text{min}}}$, separated from the $i$-th inclusive jet by a distance $\Delta R$ within a specified interval $\Delta R_{\text{min}} < \Delta R < \Delta R_{\text{max}}$ with $\Delta R = \sqrt{(\Delta y)^2 + (\Delta \phi)^2}$. For $\Delta R < \pi$, only topologies with at least three jets contribute to the numerator of Eq. (1), in pQCD, and $R_{3j}$ is computed at lowest order as a ratio of three-jet ($O(\alpha_s^3)$) and inclusive jet cross sections ($O(\alpha_s^2)$). This ratio is proportional to $\alpha_s$.

This measurement is based on a data set corresponding to an integrated luminosity of 0.7 fb$^{-1}$ collected with the D0 detector at the Fermilab Tevatron Collider. $R_{\Delta R}(p_T, \Delta R, p_{T_{\text{min}}})$ is measured in an inclusive jet sample at central rapidities $|y| < 1$ for $p_T > 50$ GeV, defined by the Run II midpoint cone jet algorithm with a cone of radius $R_{\text{cone}} = 0.7$ in $y$ and $\phi$. It is measured triple differentially, as a function of inclusive jet $p_T$, for different $p_{T_{\text{min}}}$, and in different $\Delta R$ regions. The $p_{T_{\text{min}}}$ requirements are 30, 50, 70, or 90 GeV, respectively, and the different $\Delta R$ intervals are 1.4 $< \Delta R < 1.8$, 1.8 $< \Delta R < 2.2$, and 2.2 $< \Delta R < 2.6$. For jets with $R_{\text{cone}} = 0.7$, the lower limit of $\Delta R > 1.4$ ensures that a jet does not overlap with its neighboring jets. The upper limit on $\Delta R$ is smaller than $\pi$, so that contributing neighboring jets stem only from three- (or more) jet topologies. The lowest $p_{T_{\text{min}}}$ requirement is chosen to ensure that the jet energy calibration and the jet $p_T$ resolutions are well understood. The trigger efficiencies are high for jets with $p_T > 50$ GeV in the inclusive jet sample. The requirement of $|y| < 1$ implies that $(|y| + \Delta R) < 3.6$ over the whole analysis phase space. In this rapidity region jets are well-measured in the D0 detector. The data are corrected for experimental effects and are presented at the “particle level”, which includes all stable particles as defined in Ref. [12].

A detailed description of the D0 detector can be found in Ref. [13]. The event selection, jet reconstruction, and jet energy and momentum correction follow closely those used in recent D0 measurements of inclusive jet, dijet and three-jet production rates [14–18]. Jets are reconstructed in the finely segmented liquid-argon/uranium calorimeter which covers most of the solid angle for polar angles of $1.7^\circ \lesssim \theta \lesssim 178.3^\circ$ [13]. For this measurement, events are triggered by jet triggers. Trigger efficiencies are studied as a function of jet $p_T$ by comparing the inclusive jet cross section in data sets obtained by triggers with different $p_T$ thresholds in regions where the trigger with lower threshold is fully efficient. The trigger with lowest $p_T$ threshold is shown to be fully efficient by studying an event sample obtained independently with a muon trigger. In each inclusive jet $p_T$ bin, events are taken from a single trigger which has an efficiency higher than 99%.

The position of the $p\bar{p}$ interaction is determined from the tracks reconstructed using data from the silicon detector and scintillating fiber tracker located inside a 2 T solenoidal magnet [13]. The position is required to be within 50 cm of the detector center in the coordinate along the beam axis, with at least three tracks pointing to it. These requirements discard (7–9)% of the events, depending on the trigger used. Contributions from cosmic ray events are suppressed by requiring the missing transverse momentum in an event to be less than 70% (50%) of the uncorrected leading jet $p_T$ if the latter is below (above) 100 GeV. The efficiency of this requirement for signal is found to be $> 99.5$% [14, 18]. Requirements on the characteristics of calorimeter shower shapes are used to suppress the remaining background due to electrons, photons, and detector noise that would otherwise mimic jets. The efficiency for the shower shape requirements is above 97.5%, and the fraction of background events is below 0.1% for all $p_T$, as determined from distributions in signal and in background-enriched event samples.
The jet four-momenta reconstructed from calorimeter energy depositions are then corrected, on average, for the response of the calorimeter, the net energy flow through the jet cone, additional energy from previous beam crossings, and multiple $p\bar{p}$ interactions in the same event, but not for muons and neutrinos [14, 18, 19]. The absolute energy calibration is determined from $Z \rightarrow \mu^+\mu^-$ events and the $p_T$ imbalance in $\gamma +$ jet events in the region $|y| < 0.4$. The extension to larger rapidities is derived from dijet events using a similar data-driven method. In addition, corrections in the range $(2-4)\%$ are applied that take into account the difference in calorimeter response due to the difference in the fractional contributions of quark and gluon-initiated jets in the dijet and the $\gamma +$ jet event samples. These corrections are determined using jets simulated with the PYTHIA event generator [20] that have been passed through a GEANT-based detector simulation [21]. The total corrections of the jet four-momenta vary between 50% and 20% for jet $p_T$ between 50 and 400 GeV. An additional correction is applied for systematic shifts in $|y|$ due to detector effects [14, 18]. These corrections adjust the reconstructed jet energy to the energy of the stable particles that enter the calorimeter except for muons and neutrinos.

The differential distributions $R_{\Delta R}(p_T, \Delta R, p^{\text{br}}_{T_{\text{min}}})$ are corrected for experimental effects. Particle-level events are generated with SHERPA 1.1.3 [22] with MSTW2008LO PDFs [23] and with PYTHIA 6.419 [20] with CTEQ6.6 PDFs [24] and tune QW [25]. The jets from these events are processed by a fast simulation of the D0 detector response. The simulation is based on parameterizations of jet $p_T$ resolutions and jet reconstruction efficiencies determined from data and of resolutions of the polar and azimuthal angles of jets, which are obtained from a detailed simulation of the detector using GEANT.

The $p_T$ resolution for jets is about 15% at 40 GeV, decreasing to less than 10% at 400 GeV. To use the fast simulation to correct for experimental effects, the simulation must describe all relevant distributions, including the $p_T$, $y$ and $\Delta R$ distributions for the inclusive jets and the neighboring jets. The generated events are reweighted, based on the properties of the generated jets, to match these distributions in data. To minimize migrations between inclusive jet $p_T$ bins due to resolution effects, we use the simulation to obtain a rescaling function in reconstructed $p_T$ that optimizes the correlation between the reconstructed and true values. The bin sizes in the $p_T$ distributions are chosen to be approximately twice the $p_T$ resolution. The bin purity after $p_T$ rescaling, defined as the fraction of all reconstructed events that were generated in the same bin, is above 50% for all bins. We then use the simulation to determine bin correction factors for experimental effects for all analysis bins. The correction factors are computed bin-by-bin as the ratio of $R_{\Delta R}$ without and with simulation of the detector response. These also include corrections for the energies of unreconstructed muons and neutrinos inside the jets. The total correction factors for $R_{\Delta R}$ using the reweighted PYTHIA and SHERPA simulations agree typically within 2%. The average factors, used to correct the data, are typically between 0.98 and 1.01, but never below 0.93 or above 1.03. The difference between the average and the individual corrections is taken into account as an uncertainty which is split into two contributions. One
contribution corresponds to the systematic difference between the two individual corrections, and the other one corresponds to the statistical fluctuations. The former is attributed to the model dependence and assumed to be correlated between the data points, while the latter is included in the statistical uncertainty of the results.

In total, 69 independent sources of experimental systematic uncertainties are identified, mostly related to jet energy calibration and jet $p_T$ resolution. The effects of each source are taken as fully correlated between all data points. The dominant uncertainties for the differential cross sections are due to the jet energy calibration (2–5\%), and the model dependence of the correction factors (2–3\%). Smaller contributions come from the jet $p_T$ resolution (0.5–1.5\%), the jet $φ$ resolution (0.5–2\%), and from the uncertainties in systematic shifts in $y$ (0.5–1\%). All other sources are negligible. The total systematic uncertainties are between 2\% and 6\%.

The results for $R_{ΔR}(p_T, ΔR, p_{T_{min}}^{nbr})$ are displayed in Fig. 2 as a function of inclusive jet $p_T$, in different regions of $ΔR$ and for different $p_{T_{min}}^{nbr}$ requirements. The values of $p_T$ at which the data points are presented correspond to the geometric bin centers. A detailed documentation of the results, including the individual uncertainty contributions, is provided in the supplementary material. For a given $ΔR$ region, and $p_{T_{min}}^{nbr}$, $R_{ΔR}$ increases with $p_T$ up to a maximum value, above which it falls when approaching the kinematic limit. At fixed $p_T$, $R_{ΔR}$ increases with $ΔR$ and decreases with increasing $p_{T_{min}}^{nbr}$. At lower $p_T$, $R_{ΔR}$ depends more strongly on $p_{T_{min}}^{nbr}$. For larger $p_{T_{min}}^{nbr}$, both the $p_T$ and the $ΔR$ dependencies are stronger.

The theory predictions for $R_{ΔR}$ which are compared to the data, and which are later used to extract $α_s$, are given by the product of the NLO pQCD results and correction factors for non-perturbative effects, including hadronization and underlying event. The non-perturbative corrections are determined using PYTHIA 6.425 with tunes AMBT1 [26] and DW [27], which use different parton shower and underlying event models. The hadronization correction is obtained from the ratio of $R_{ΔR}$ at the parton level (after the parton shower) and the particle level (including all stable particles), both without underlying event. The underlying event correction is computed from the ratio of $R_{ΔR}$ computed at the particle level with and without underlying event. The total corrections are defined as the combination of the corrections due to hadronization and the underlying event and they vary between +10\% and −3\% for tune AMBT1 and between −1\% and −10\% for tune DW. The results obtained with the two tunes agree typically within (2–4\%) and always within 11\%. The central results are taken to be the average values, and the uncertainty is taken to be half of the difference (given in the supplementary material). As a cross-check, the non-perturbative corrections have also been derived with HERWIG 6.520 [28, 29]. The HERWIG results are consistent with the results from the
PYTHIA tunes AMBT1 and DW for all kinematic regions considered in this analysis.

The NLO pQCD prediction is given by the ratio of an inclusive three-jet cross section and the inclusive jet cross section both evaluated at their respective NLO. The numerator and the denominator both depend on the PDFs and most of the PDF dependencies cancel in the ratio. A residual PDF dependence remains, due to small differences in the decompositions of the partonic subprocesses and a slightly different coverage of proton momentum fractions $x$ in the numerator and the denominator. While the PDFs have no explicit $\alpha_s$ dependence, their knowledge (i.e. PDF parameterizations) depends implicitly on $\alpha_s$ due to assumptions on $\alpha_s$ during the extraction procedure. Therefore, the pQCD prediction for $R_{\Delta R}$ has an explicit $\alpha_s$ dependence stemming from the ratios of three-jet and inclusive jet matrix elements, and an implicit $\alpha_s$ dependence due to the residual dependence on the PDFs.

The NLO pQCD results are computed using fastnlo [30] based on nlojet++ [31, 32], in the MS scheme [33] for five active quark flavors. The calculations use the next-to-leading logarithmic (two-loop) approximation of the RGE and $\alpha_s(M_Z) = 0.118$ in the matrix elements and the PDFs, which is close to the current world average value of 0.1184 [4]. The central choice $\mu_0$ for the renormalization and factorization scales is the inclusive jet $p_T$, $\mu_R = \mu_F = \mu_0 = p_T$, and the MSTW2008NLO PDFs [23] are used.

The uncertainties of the pQCD calculations due to uncalculated higher order contributions are estimated from the $\mu_{R,F}$ dependence. These are computed as the relative changes of the results due to independent variations of both scales between $\mu_0/2$ and $2\mu_0$, with the restriction of $0.5 \leq \mu_R/\mu_F \leq 2.0$. These variations affect the theory results by (3–9)%. The PDF uncertainties are computed using the up and down variations of the 20 orthogonal PDF uncertainty eigenvectors, corresponding to the 68% C.L., as provided by MSTW2008NLO. The $R_{\Delta R}$ results obtained with the CT10 [34] and NNPDFv2.1 [35] PDF parameterizations agree with those for MSTW2008NLO typically within 1% and always within 3%.

The theory results are compared to the data in Fig. 1 and the ratios of data and theory are displayed in Fig. 2 for all twelve kinematic regions in $\Delta R$ and $p_{T_{\text{min}}}^{\text{nbr}}$. The PDF uncertainties are (2–5)% and the scale uncertainties are typically (4–8)% for $p_{T_{\text{min}}}^{\text{nbr}} \leq 50, 70,$ and 90 GeV. The theoretical predictions are in good agreement with data and the ratios are independent of $p_T$, $\Delta R$, and $p_{T_{\text{min}}}^{\text{nbr}}$. For $p_{T_{\text{min}}}^{\text{nbr}} = 30$ GeV, the predictions are systematically below the data by (8–15)%. This might be caused by limitations of either the perturbative calculation or the modeling of the non-perturbative effects at low $p_{T_{\text{min}}}^{\text{nbr}}$.

These $R_{\Delta R}$ results are then used to determine $\alpha_s$ and to test the two-loop RGE prediction for its running as a function of the scale $p_T$. In an initial study, the data are split into 12 subsets defined by the different $(\Delta R, p_{T_{\text{min}}}^{\text{nbr}})$ requirements. Assuming the RGE, the value of $\alpha_s(M_Z)$ is fitted to each of these subsets, and the corresponding $\chi^2$ values are determined that compare data and theory. Since each of these subsets covers a large inclusive jet $p_T$ range, a violation of the RGE would be reflected in poor $\chi^2$ values. Furthermore, the comparison of the extracted $\alpha_s(M_Z)$ values allows the study of the dependence of the results on $\Delta R$ and/or $p_{T_{\text{min}}}^{\text{nbr}}$. The data from kinematic regions in $(\Delta R, p_{T_{\text{min}}}^{\text{nbr}})$ in which the $\alpha_s(M_Z)$ fit results are consistent with each other are then used in the subsequent analysis. These data are split into 12 groups, each with the same inclusive jet $p_T$, combining data points for different $(\Delta R, p_{T_{\text{min}}}^{\text{nbr}})$. For each group, $\alpha_s$ is determined at the corresponding $p_T$, and then evolved, using the RGE, to $\mu_R = M_Z$.

The $\alpha_s$ extraction requires the theory predictions to be available as a continuous function of $\alpha_s$, used in the matrix elements and PDFs. The global PDF fits [23, 34, 35] do not provide the full $\alpha_s$ dependence of their results, but only PDF sets at discrete values of $\alpha_s(M_Z)$, in increments of $\Delta \alpha_s(M_Z) = 0.001$. A continuous $\alpha_s(M_Z)$ dependence for $R_{\Delta R}$ is obtained, by cubic interpolation (linear extrapolation) of the theory results inside (outside) the available $\alpha_s(M_Z)$ range. For the central results, we use MSTW2008NLO PDFs which cover the largest range of $0.110 \leq \alpha_s(M_Z) \leq 0.130$. The fits determine $\alpha_s$ by using MINUIT [36] to minimize the $\chi^2$ function [37] calculated from the differences between theory and data. All correlated systematic experimental and theoretical uncertainties are treated in the Hessian approach [37], except for the uncertainty due to the $\mu_{R,F}$ dependence. The correlated statistical uncertainties are taken into account via the covariance matrix. The $\alpha_s$ results are obtained by minimizing $\chi^2$ with respect to $\alpha_s$ and the nuisance parameters for the correlated uncertainties. By scanning

χ^2 as a function of α_s, the uncertainties are obtained from those α_s values for which χ^2 is increased by one with respect to the minimum value. Fits, that determine α_s(M_Z) use the two-loop solution of the RGE to translate α_s(M_Z) values to the corresponding values of α_s(p_T) which enter the pQCD calculations for the different p_T bins. These α_s(M_Z) results are therefore derived assuming the validity of the RGE. Those fits that extract α_s(p_T) from a group of data points in the same p_T bin are almost independent of the RGE. A small dependence on the RGE enters only due to the residual dependence of the R_ΔR predictions on the PDFs which use the RGE in their DGLAP evolution. Otherwise these α_s(p_T) fit results are independent of the RGE.

In the α_s determination, we consider the correlations of the statistical uncertainties and all 69 sources of correlated experimental systematic uncertainties. The theory uncertainties include the uncertainties of the non-perturbative corrections, the PDF uncertainties and the μ_{R,F} dependence of the pQCD calculations. Following Refs. [38,40], the uncertainty due to the μ_{R,F} dependence is computed by repeating the α_s fit for different choices of μ_{R,F} and the largest difference to the central result (obtained for μ_{R,F} = p_T) is taken to be the corresponding uncertainty for α_s. The α_s fits are also repeated for CT10 and NNPDFv2.1 PDFs, and the largest differences are quoted as “PDF set” uncertainty. The uncertainties from the scale variation and from the different PDF sets are added in quadrature to the other uncertainties to obtain the total uncertainty.

Before the central α_s results are obtained, the consistency of the individual results for the 12 different (∆R, p_T^{min}) regions, listed in Table I is tested. Assuming the RGE, the values of α_s(M_Z) are fitted to each of the 12 subsets, and listed in Table I together with the corresponding χ^2 values. All χ^2 values are consistent with the expectations based on the number of degrees of freedom (N_{dof}), χ^2 = N_{dof} ± √2 N_{dof}. This means that the RGE is consistent with the observed p_T dependence of α_s(p_T) over the studied p_T range in all ∆R regions and for all p_T^{min}. For the same p_T^{min}, the α_s(M_Z) results for different ∆R regions are consistent with each other, i.e. there is no ∆R dependence. The α_s(M_Z) results are rather independent of p_T^{min} for p_T^{min} ≥ 50 GeV. Only the α_s(M_Z) results for the lowest requirement, p_T^{min} = 30 GeV, are significantly higher. As mentioned earlier, at lowest p_T^{min} limitations of the perturbative calculations or the non-perturbative models may become visible. The data with p_T^{min} = 30 GeV are therefore excluded when the final results of this analysis are determined.

All remaining data points with the same p_T (from all three ∆R regions and for p_T^{min} = 50, 70, and 90 GeV) are combined to fit α_s(p_T), at the p_T value corresponding to the geometric center of the bin. This is done for all 12 different p_T bins in the range 50 < p_T < 450 GeV and the results are listed in Table II and displayed in Fig. 3 (a). Using the RGE, the individual results are then evolved to μ_R = M_Z, and shown in Fig. 3 (b). These α_s results from R_ΔR, extracted using NLO pQCD, are in good agreement with our previous results from inclusive jet cross section data [38], extracted using NLO plus 2-loop contributions from threshold corrections [42], and with the results from a reanalysis of event shape data from the ALEPH experiment at the LEP e^+e^- collider, extracted using NNLO calculations [41]. A combined fit, using the same data set integrated over p_T, and for MSTW2008NLO PDFs, gives the α_s(M_Z) result listed in Table III. The results obtained for CT10 PDFs (α_s(M_Z) = 0.1189) and NNPDFv2.1 (α_s(M_Z) = 0.1167) are used to define the uncertainty due to the PDF set. This result is in good agreement with our previous result of α_s(M_Z) = 0.1161^{+0.0041}_{-0.0048}, obtained from inclusive jet cross section data at p_T < 145 GeV [3], and the world average value [4]. The RGE prediction for this result is displayed in Fig. 3 (a). The new α_s(p_T) results from R_ΔR
The new momentum transfers, \( p_{\text{br}} \), the minimal transverse momentum of the neighboring jet region, are well described by the RGE prediction including the region \( 208 < \mu_R < 400 \) GeV, in which the RGE is tested for the first time.

In summary, a measurement has been presented of a new quantity \( R_{\Delta R} \) which probes the angular correlations of jets. \( R_{\Delta R} \) is measured as a function of inclusive jet \( p_T \) in different annular regions of \( \Delta R \) between a jet and its neighboring jets and for different requirements on the minimal transverse momentum of the neighboring jet \( p_{\text{br}} \). The data for \( p_T > 50 \) GeV are well-described by pQCD calculations in NLO in \( \alpha_s \) with non-perturbative corrections applied. Results for \( \alpha_s(p_T) \) are extracted using the data with \( p_{\text{br}}^{\text{min}} \geq 50 \) GeV, integrated over \( \Delta R \). The extracted \( \alpha_s(p_T) \) results from \( R_{\Delta R} \) are, to good approximation, independent of the PDFs and thus independent of assumptions on the RGE. Therefore, these \( \alpha_s \) results are the first to provide a test of the RGE at minimal transverse momentum transfers up to 400 GeV. The combined \( \alpha_s(M_Z) \) result, obtained using the data with \( p_{\text{br}}^{\text{min}} \geq 50 \) GeV (integrated over \( \Delta R \) and \( p_T \)), is \( \alpha_s(M_Z) = 0.1191^{+0.0048}_{-0.0071} \), in good agreement with the world average value \( [4] \).
