Abstract

**Background:** Optimal healthcare access improves people's health status and decreases health inequalities. Many studies demonstrated spatial access importance in health outcomes. Recent studies assessed spatial healthcare access using the enhanced two-step floating catchment area (E2SFCA) method. The aim of this study was to build a hospital facility access indicator at a fine geographic scale and to determine whether there is a complementarity between non-hospital and hospital care accessibility by investigating the length of hospital stays (LOS).

**Methods:** This study focused on the ≥75-year-old population of the Nord administrative region of France. Hospital spatial accessibility was computed with the E2SFCA method, and then the LOS score was calculated from the French national hospital activity and patient discharge database. Linear regression models were used to analyze the relationship between LOS and spatial accessibility to hospital-based care and to the three types of non-hospital care services (general practitioners, physiotherapists, and home-visiting nurses).

**Results:** Overall, there were 19.0 beds in Medical, Surgical and Obstetrics (MCO) facilities and 5.58 beds in Postoperative and Rehabilitation Care facilities (SSR) per 10,000 inhabitants, but with important geographic variations. Accessibility to hospital services was higher for people in large urban areas, despite the dense population and the higher demand. In 2014, the mean LOS scores were 0.26 for MCO and 0.85 for SSR, with a non-homogeneous geographical repartition. Linear regression analysis revealed a strong negative and significant association between hospital and non-hospital care accessibility.
Conclusions: This is the first study to measure spatial accessibility to hospital-based cares in France using the E2SFCA method, and the first to investigate the relationship between spatial accessibility to hospital-based care facilities and three types of non-hospital care services and healthcare utilization (LOS). Our findings should help to take decisions about deploying additional beds and to identify the best locations for non-hospital care services. Moreover, they should also help to improve access, and to ensure the best coordination and sustainability of inpatient and outpatient services, in order to better cover the population’s healthcare needs. Other international studies using multiple consensual indicators of healthcare outcomes and accessibility and sophisticated modeling methods should be developed.

Keywords: Potential accessibility, hospital care, non-hospital care, length of stay, E2SFCA, administrative data uses
1. **BACKGROUND**

Access to healthcare is widely recognized as the foundation of any high performing healthcare system. Ensuring a high degree of healthcare access improves people's health status and decreases health inequalities. Guaranteeing equal accessibility to healthcare facilities for everyone is an essential goal for international political organizations and national governments [1-5].

Access to healthcare can be determined by two complementary dimensions: spatial and non-spatial dimensions [6]. Spatial access varies across space and time, and consequently it is affected by location relationships and travel impedance. On the other hand, non-spatial access mainly focuses on socioeconomic conditions and cultural background, such as ethnicity, income, social class, education, and language ability [7]. Many studies have demonstrated that spatial access plays an important role in health outcomes [8-13].

The assessment of spatial access to healthcare services should take into account the care provided by various facility types. Indeed, in many countries, the healthcare system is based on a combined architecture: non-hospital care based on general practitioners who can address patients to other healthcare professionals (e.g. nurses, physiotherapists, specialists doctors) and hospital-based care [14, 15]. Non-hospital care represents the most significant primary care contributor in many countries, including developing countries [16,17], because it ensures an effective and generally faster service that covers the large majority of personal healthcare needs [18], and acts as the principal point of continuing care for patients [19]. Nevertheless, hospitals remain one of the key actors. Care provided by hospitals represents
a major part of people’s consumption of healthcare and medical goods, especially in Europe. In 2017, nine of the ten countries with the highest hospital discharge rates worldwide were European Union member states [20]. Therefore, coordination and organization between hospital and non-hospital care are critical for a successful healthcare system. This is particularly true during pandemic situations when hospitals may reach a point of "complete saturation" due increased influx of patients, and non-hospital resources may anticipate and limit the number of hospitalizations and the consumption of hospital-linked resources [21, 22]. Therefore, it is essential to assess accessibility to non-hospital care and hospital-based care and also to examine whether there is a complementarity relationship between these care types [23].

In parallel, the complementarity between accessibility to self-employed practitioners and to hospital facilities should be investigated also by analyzing healthcare utilization, as done in many studies [24, 25]. Medical administrative databases are appropriate to analyze healthcare utilization [26]. Traditionally, healthcare utilization has often been expressed in terms of health outcomes and healthcare service volume. For instance, one classical indicator is the length of hospital stays that can be interpreted as an indicator of healthcare supply and treatment efficiency [15, 27-29]. Thus, it can be recognized as an indicator of the quantity and quality of the healthcare delivered by the healthcare system.

In this context, the aim of this study was to analyze the spatial accessibility to hospital-based care following three main complementary steps: 1) to build a hospital facility access indicator at a fine geographic scale; 2) to measure health service utilization using the length of hospital stays; and 3) to determine whether there is a complementarity between non-
hospital and hospital care accessibility. This analysis focused on the ≥75-year-old population of the Nord administrative region of France. Indeed, in many countries including France, elderly people represent a growing proportion of the total population with an increasing number of age-related diseases. The challenge is to respond to their demand by offering healthcare adapted to their specific needs. Additionally, different healthcare sources are involved in the elderly patients’ management: hospital facilities, and non-hospital care (e.g. general practitioners, physiotherapists, and home-visiting nurses).

The hospital facility access indicator (step 1) was built using the enhanced two-step floating catchment area (E2SFCA) method, one of the most widely used gravity-based approaches. Based on this method, two different spatial indicators have been constructed in France: the localized potential accessibility score developed by the French Research Institute in Health Economic institute (IRDES) at the municipality level in 2011 [30], and at the census block level for the Greater Paris area in 2019 [31]. In 2016, the index of spatial accessibility (ISA) at the census block level was implemented by Gao and al. [32]. However, one common limitation of these studies was the focus on non-hospital care services only. So far, no French indicator based on the E2SFCA method measured access to hospital healthcare at a very fine geographic scale.

2. METHODS

2.1. Study setting and population

This study was carried out in the Nord administrative region that is located in the north of France, with a surface area of 5743 km² and a population density of 456 inhabitants per km². Multiple non-hospital care accessibility indicators are available for this department [30-32].
Moreover, it has been shown that edge effects lead to minor accessibility variations in this area [33]. The study focused on the ≥75-year-old population of this area.

2.2. Data sources and statistical unit

Multiple data sources were combined for the present study:

(1) The accessibility to three types of non-hospital, self-employed practitioners (general practitioners, physiotherapists, and home-visiting nurses) was described using the Localized Potential Accessibility (Accessibilité potentiellement localisée: APL) database [34]; Based on E2SFCA method, APL indicators are available at national level but only computed for non-hospital practitioners.

(2) The number of available beds in each hospital was extracted from the Annual Statistical Survey of Healthcare Facilities 2014 database (Statistique Annuelle des Établissements: SAE) [35]. Facilities were classified in two categories: Medical, Surgical and Obstetrics facilities (Médecine, Chirurgie, Obstétrique: MCO) and Postoperative and Rehabilitation Care facilities (Soins de Suite et de Réadaptation: SSR);

(3) The postal address of each hospital was obtained from the National File on Health and Social Institutions (Fichier national des établissements sanitaires et sociaux: FINÉSS) [36], and then converted into latitude and longitude using the French National Address Base [37];

(4) The Length Of Stay (LOS) was calculated from the French national discharge database that collects hospital activity and patient discharge data [38-41]. We used MCO and SSR inpatient care data for the year 2014;
(5) The number of ≥75-year-old people in the Nord administrative region was obtained from the 2016 French national Census [42].

The statistical unit was the French Geographic Code unit (FGC), defined by the French national discharge database. The FGC is approximately equivalent to the municipality postal code. The Nord department is divided into 240 FGCs with a population ranging from 1000 to 227 000 residents per FGC.

2.3. Methodology

First, the E2SFCA method was implemented to compute the hospital spatial accessibility by combining geographical, supply, and demand factors. Second, the LOS indicator was estimated for each FGC unit. Third, linear regression models were used to analyze the relationship between LOS and spatial accessibility to hospital-based care and also to the three types of non-hospital care services (general practitioners, physiotherapists, and home-visiting nurses).

2.3.1. Assessing hospital care spatial accessibility using the E2SFCA method

The E2SFCA method [43] was implemented to assess spatial accessibility [5, 32, 44], which can be easily interpreted as medical care density. The method was implemented in two steps, as follows:

Step1: For each hospital center \( j \) with a MCO or SSR facility, the number of beds in the MCO or SSR facility \( S_j \) was counted and the population living in the FGC area \( k \) and located within
a threshold drive time $d_{max}$ from the hospital center $j$ (i.e. catchment area $j$) was estimated.

Then, the bed-to-population ratio $R_j$ within the catchment area $j$ was determined with Equation 1:

$$R_j = \frac{S_j}{\sum_{k \in \{d_{kj} \leq d_{max}\}} P_k \cdot w(d_{kj})}$$  \hspace{1cm} \text{Equation (1)}$$

where $P_k$ is the patient population in the FGC area $k$ the centroid of which falls within the catchment area $j$ (i.e. $d_{kj} < d_{max}$), $S_j$ is the number of beds available in the hospital center $j$, and $d_{kj}$ is the driving time between the FGC area $k$ and the hospital center $j$, and $w(\cdot)$ is a weighted decay function that depends on the driving time $d_{kj}$.

Step 2: For each population location $i$, all MCO or SSR facility locations $j$ that were within the threshold driving time $d_{max}$ from location $i$ (i.e. catchment area $i$) were estimated, and all $R_k$ for the catchment area were summed to calculate the Index of Spatial Accessibility ($A_i$) at location $i$ (Equation 2):

$$A_i = \sum_{j \in \{d_{ij} \leq d_{max}\}} w(d_{ij}) R_j$$  \hspace{1cm} \text{Equation (2)}$$

where $R_j$ is the bed-to-population ratio of the hospital center $j$ and $d_{ij}$ is the driving time between the FGC area $i$ and the hospital center $j$.

All driving times from $i$ to $j$ were obtained using Google Maps and then computed by SAS version 9.3 [45]. The E2SFCA accessibility score was calculated with the MYSQL program. The definition of the decay function $w(\cdot)$ and time thresholds were previously explained [32].

Briefly, when the travel time to a MCO and to a SSR facility was longer than 41 and 69
minutes, respectively, that hospital was considered too distant to be accessible. These distance decay parameters were used as cut-off distances to define the catchment areas.

\[ \text{LOS}_i = \sum_{g > 75} \frac{dms_g}{Pg} \]  

Equation (3)

2.3.2. Measuring health service utilization using the LOS indicator

The LOS was defined as the mean hospital stay length of elderly people (≥75 years of age) relative to the total ≥75-year-old population in a given FCG (Equation 3). In this equation, \( g \) represents the three groups of ≥75-year-old people (75-84, 85-94 and >95 years), and \( Pg \) the corresponding total population for that age group. The numerator represents the average length of stay of each age group, standardized to the total population for that age group (inpatients or not) in the denominator.

2.3.3. Linear Regression Model and composite accessibility indicator by principal component analysis

A multiple ordinary least squares regression model was applied to investigate the relationship between MCO and SSR LOS (Y: the dependent variable) and the hospital accessibility indicators (MCO and SSR ISA) and the APL for the three non-hospital practitioners (general practitioners, physiotherapists, and home-visiting nurses) as regressors (Equation 4). As our variables were log-normally distributed, they were normalized using the logarithmic Napierian function.
$ln(LOS^*) = \beta_0 + \beta_1.ln(ISA^*) + \sum \beta_n.ln(APL_n) + \varepsilon; \text{ with } \varepsilon \approx iid(0; \sigma^2)$ \hspace{1cm} \text{Equation (4)}

1

Where * signifies that the LOS for MCO (with the corresponding ISA as independent variable) and for SSR (with the corresponding ISA as independent variable) were modeled separately, and $n$ defines the number of different types of non-hospital healthcare professionals considered in the analysis ($n=3$: general practitioners, physiotherapists, and home-visiting nurses).

7

To describe the global accessibility to the three non-hospital services, a composite index was built using principal component analysis (Equation 5).

$ln(LOS^*) = \beta_0 + \beta_1.ln(ISA^*) + \beta_2.ln(Composite APL) + \varepsilon; \text{ with } \varepsilon \approx iid(0; \sigma^2)$ \hspace{1cm} \text{Equation (5)}

11

3. RESULTS

3.1 Descriptive analysis and spatial distribution of the ISA values for MCO and for SSR facilities

In total, there were 240 FGC units in the Nord administrative region. Table 1 summarizes the ISA values for MCO and SSR facilities. On average, there were 19.0 beds in MCO and 5.58 beds in SSR for 10 000 inhabitants. The values revealed important variations among FGCs with a standard deviation of 10.6 and 2.23 beds per 10 000 inhabitants in MCO and SSR,
respectively. Almost 25% of the population had access to fewer than 10 beds in MCO and 4 beds in SSR.

To compare the spatial distribution of the ISA values for MCO (a) and SSR (b) per 10 000 inhabitants (Figure 1) within the Nord administrative region, scores were categorized in five classes using the Jenks Natural Breaks algorithm, from low to high accessibility. The Jenks Natural Breaks algorithm assigns values to a given number of classes with the objective of minimizing the variance within classes, while maximizing the between-class means. The highest MCO ISA values ([24.04; 32.71] and [32.72; 39.28]) were observed in urban areas located in the northern part of the studied territory, close to Dunkerque, and also in the center, around Lille, Roubaix and Tourcoing. Conversely, the lowest values were observed mostly in the southern part and around Hazebrouck. The highest ISA scores for SSR ([6.05; 7.14] and [7.14; 9]) were concentrated in the middle part of the region, whereas access was lower in the north and south. These findings showed that accessibility to hospital services is higher for people in large urban areas, despite the dense population and consequently the higher demand.

3.2 Elderly population and LOS spatial distribution

The elderly population was not homogeneously distributed over the studied territory. The percentage of ≥75-year-old inhabitants varied from 3.79% (in the north-west area around Dunkerque, and in the center, particularly the cities of Roubaix, Lille and Villeneuve d’Ascq) to 11.91% (around Bailleul and Hazebrouck and below the Valenciennes-Cambrai line) (Figure 2).
Analysis of the LOS in MCO and SSR facilities for the ≥75-year-old population in the Nord administrative region (Table 2) showed that in 2014, the mean LOS were 0.26 and 0.85 for MCO and SSR, respectively. The spatial variation was important, with standard deviations of 0.20 and 0.92 for MCO and SSR, respectively.

Analysis of the MCO and SSR LOS score distribution in the studied region highlighted a non-homogeneous repartition with higher values close to the border with other French regions, especially in the southern part (Figure 3 and Figure 4). From Dunkerque to Bailleul and also around Tourcoing, Roubaix, Lille and Orchies, LOS scores were lower. This suggests the existence of spatial dependencies in LOS distribution within the studied territory. This hypothesis was confirmed with the Moran test (p-value = 0.000 for both MCO and SSR LOS scores).

3.3 Determinants of MCO and SSR LOS

To investigate the determinants of MCO and SSR LOS scores separately, two independent least square regression models were implemented at the FGC scale, including the covariates presented in the Data sources section. The LOS variable was log transformed to normalize its distribution.

The three APL variables were based on the activity level of these self-employed general practitioners and on the healthcare utilization rates in function of the inhabitant age group in order to estimate more precisely the healthcare supply and demand in a given territory. A composite APL was integrated in the Linear Regression Model to better describe the overall non-hospital care service accessibility. This analysis revealed a strong negative and significant association between the composite APL and the MCO and SSR LOS (Table 3).
Furthermore, the MCO ISA showed that LOS were shorter for patients living in areas where people had easier access to a MCO facility.

4. DISCUSSION

4.1 Summary of the results

To our knowledge, the present study is the first one to investigate the relationship between spatial accessibility to hospital-based care facilities (ISA index) and to three types of non-hospital care services (APL index for general practitioners, physiotherapists, and home-visiting nurses) and healthcare utilization based on a national hospital database (LOS). One of its main strengths is the cross-referencing of different data sources that allowed us to address several major public health issues.

First, following a previously developed methodology [32, 43], we estimated a measure of spatial accessibility to hospital care, for MCO and SSR facilities separately at the French Geographic Code scale (FGC, approximately equivalent to the municipality scale). However, all previous French studies that used a similar methodology limited their accessibility measure to non-hospital care services [30-32]. The present study originality lies in extending the measure to hospital spatial accessibility, by taking into account the number of beds in MCO and SSR facilities, the car travel time, and the population distribution. The MCO and SSR ISA were initially developed at the census block scale, then summarized to the FGC scale to investigate the association with the LOS indicator, because FGC is the smallest spatial level for which hospital data are available. Even at this spatial scale, ISA distribution
highlighted the unequal accessibility to MCO and SSR facilities within the study area. Analysis of ISA spatial distribution revealed that high-accessibility areas were mainly concentrated in the center of the investigated area. This can be partially explained by the large number of MCO and SSR facilities (25 of the 44 MCO and 24 of 30 the SSR centers) in these areas. However, we observed exceptions. Around Valenciennes, where there are three MCO hospitals with more than 400 beds in total, the ISA values were in the lower class. Conversely, although no MCO facility was located in or close to Bailleul, the ISA value for this area was quite high. This finding is coherent with the fact that the ISA index provides a summary measure of two important and related components of accessibility: the volume of services available relative to the population size, and the proximity of services available relative to the population location. Therefore, although 400 MCO beds were located close to Valenciennes, the population's size was too important to obtain a high accessibility score.

Then, we examined the association between the healthcare utilization indicator (LOS) and two accessibility scores (ISA and APL). Our analysis revealed a significant and negative association between LOS and spatial accessibility to the three non-hospital care services (general practitioners, physiotherapists, and home-visiting nurses). In other words, a better accessibility to these non-hospital services corresponded to shorter hospital stays. This suggests that hospital-based care facilities and non-hospital care services interact in a complementary way. One explication is that in areas with better accessibility to the three non-hospital care services, hospitalizations are shorter because of the presence of effective outpatient care: ambulatory care and neighborhood healthcare services. For instance, home-visiting nurses and physiotherapists could be an alternative solution to SSR inpatient care. These results further support the idea of complementary interactions between non-hospital
and hospital services. These first findings should be complemented by research to determine the impact of primary care accessibility on LOS.

4.2 Comparison with the international literature

Previous studies have paid attention to healthcare spatial accessibility and the question of whether healthcare activity could be rebalanced by expanding/strengthening the role of primary care relative to the more costly hospital (secondary) care. However, much of the recent research on geographic healthcare access has focused on assessing the potential access to healthcare services, rather than on their utilization [46, 47]. Most studies that focused on the use of primary care to reduce specialty/inpatient care were observational studies in which the rates of preventable hospitalizations were correlated with the self-rated access level [48] or distance [49, 50] to primary care services [51]. Few studies quantified both hospital and non-hospital care spatial accessibility with the E2SFCA method, and investigated their association with the length of hospital stay. The present study fills this gap by integrating three factors: spatial accessibility (1) to hospital care facilities and (2) to three types of non-hospital care (general practitioners, physiotherapists, and home-visiting nurses), and (3) length of hospital stays. As few studies have considered all three with a similar study design, comparison with the international literature was difficult. However, we could find few studies that investigated one or two of these aspects. First, although this is the first French study measuring hospital spatial accessibility using the E2SFCA method, other countries, for instance China [52] and Japan [44], already developed hospital accessibility scores following a similar approach. Second, other studies estimated the LOS to
assess how primary care could contribute to reduce the demand of secondary care. In France, a study used the LOS for public-sector psychiatric facilities to investigate whether the development of alternatives to full-time hospitalization (such as ambulatory care, part-time hospitalization, and full-time outpatient care) may reduce the LOS [15]. They found a significant negative association and concluded that their study was the first to provide nation-wide evidence of the benefits of alternatives to full-time hospitalization in psychiatry. Similarly, our study is the first to show that non-hospital care services may reduce the MCO and SSR LOS. Our findings and those of this study in psychiatry suggest that in some cases, non-hospital care services may constitute an alternative to hospitalization. Our results were obtained by modeling the association between healthcare utilization and accessibility to two types of healthcare services. These preliminary quantitative results should be supplemented by data on other healthcare outcomes frequently associated with the quality of care, such as unplanned readmission or mortality, as well as other aspects of accessibility (e.g. multiple consensual indicators of spatial/non-spatial healthcare access). Additional studies using sophisticated modeling methods should also be developed. The goal is to develop a consolidated approach to facilitate the spatial organization of non-hospital medical services in the territory with the aim of complementing hospital services and increasing healthcare efficiency.

4.3 Limitations

As we used aggregated data at the FGC scale to assess associations between spatial accessibility to hospital and to three types of non-hospital care services and healthcare utilization, our findings may be subject to an ecological bias [32]. In addition, as previously explained, while the ISA index was estimated at the census block scale, the two other
indicators (LOS and APL) were only available at the FGC scale, a cruder spatial scale. Thus, we could not take into account the spatial accessibility heterogeneity at the census block scale.

For future research, we want to construct a LOS indicator at a finer scale using disaggregation techniques that take into account the population density.

In our analysis, we did not use statistical techniques that consider spatial autocorrelation. However, at the FGC scale, the Moran’s indicator revealed the presence of spatial autocorrelation for both MCO and SSR LOS. To investigate more precisely the association of healthcare accessibility and utilization, the next step could be to consider the specificity of the study area by including its topological, geometric and geographic properties using spatial statistical models, such as the simultaneous autoregressive model, geographically weighted regression and Bayesian hierarchical model. Previous studies [53-57] demonstrated the robust properties of these models that can improve the methodology used to assess associations between healthcare spatial accessibility and utilization. For instance, Nicholas et al used Bayesian spatial models and location analysis methods to evaluate healthcare facility access [58].

5. CONCLUSION

This is the first study to measure spatial accessibility to MCO and SSR facilities in France using the E2SFCA method and to investigate the relationship between spatial accessibility to hospital-based care facilities and to non-hospital care services. It provides a basic understanding of the status of inpatient care within the studied area by showing the accessibility score variation across the territory and highlighting some areas with poor accessibility. This type of information is important to guide policy makers and local
managers. Moreover, our findings suggest that hospital-based and non-hospital care services (general practitioners, physiotherapists, and home-visiting nurses) interact in a complementary way. Based on this research, policy makers and local managers could identify areas where additional beds or healthcare professionals should be allocated in priority.

Additional studies in other areas characterized by their own specificity have to be developed in order to confirm our results. It is also crucial to design new research approaches to understand the underlying mechanisms and processes that explain the interaction between hospital-based and non-hospital care services with the ultimate objective of better organizing and allocating medical resources. This research should help to take decisions about deploying additional beds and identifying the best locations for non-hospital care services, and also to improve access, to ensure the best coordination and to contribute to the sustainability of inpatient care and outpatient services, in order to better cover the health needs of the population.

LIST OF TABLES

Table 1: Descriptive analysis of the Index of Spatial Accessibility (ISA) for MCO and SSR.
Nord administrative region (expressed for 10,000 inhabitants).

|       | N   | Min | Mean (Sd)     | Max  | 25th | Median | 75th |
|-------|-----|-----|---------------|------|------|--------|------|
| MCO   | 240 | 0.44| 19.0 (10.69)  | 39.28| 10.28| 14.32  | 29.41|
| SSR   | 240 | 0.03| 5.58 (2.19)   | 9.00 | 4.25 | 6.33   | 7.25 |

Sd, standard deviation

Table 2. LOS of ≥75-year-old people in MCO and SSR facilities – Nord administrative region.

|       | N   | Min | Mean (Sd*) | Max  | 25th | Median | 75th |
|-------|-----|-----|------------|------|------|--------|------|
| MCO   | 240 | 0.01| 0.26 (0.20)| 1.68 | 0.10 | 0.20   | 0.37 |
| SSR   | 240 | 0.03| 0.85 (0.92)| 10.98| 0.33 | 0.65   | 1.08 |

* Standard deviation

Table 3: Summary of the two regressions models: the MCO and SSR LOS scores at FGC scale.

|                     | MCO LOS score | SSR LOS score |
|---------------------|---------------|---------------|
| COMPOSITE APL       | -1.141***     | -1.379***     |
| MCO ISA             | -.283**       | NA            |
| SSR ISA             | NA            | .045          |
| Observations        | 240           | 239           |
| R²                  | 0.134         | 0.082         |
| VIF                 | <1.17         | <1.13         |

** p<0.01; *** p<0.001; R²: determination coefficient; VIF: Variance Inflation Factor; NA: Not applicable
**FIGURE LEGENDS**

Fig. 1 Spatial distribution of the Index of Spatial Accessibility at the FCG level. (a) Index of Spatial Accessibility for Medical, Surgical and Obstetrics (MCO) and (b) Post-operative and Rehabilitation Care (SSR) centers. For each map, the French neighboring administrative regions are colored in green, whereas the Nord administrative region is represented using a graduated color approach, to highlight the different ISA scores.

Fig. 2 Distribution of the ≥75-year-old population at the FGC level in Nord administrative region in 2016.

Fig. 3 MCO LOS spatial distribution for ≥75-year-old people at the FGC level. LOS for Medical, Surgical and Obstetrics (MCO) centers

Fig. 4 SSR LOS spatial distribution for ≥75-year-old people at the FGC level. LOS for Post-operative and Rehabilitation Care (SSR) centers
