RESUMEN

Se presenta una serie de simulaciones de \(N\)-cuerpos destinadas a estudiar la dinámica de grupos pequeños de galaxias. En particular, se comparan los resultados obtenidos con las propiedades dinámicas de los grupos de Hickson. Se consideran condiciones iniciales partiendo de una ‘expansión máxima’ y de equilibrio virial, y no se considera un halo oscuro común primigenio. Se encuentra muy buena concordancia con las propiedades de grupos pequeños de galaxias, y las propiedades de los grupos compactos de Hickson son reproducidas adecuadamente por aquellos sistemas que se encuentran en un estado avanzado de un colapso gravitacional. No se encuentra un problema de ‘sobre-fusión’ de las galaxias. Para grupos que comienzan en virial, se encuentra que una fracción importante (\(\sim 40\%\)) pueden durar por \(\sim 10\) Gyr sin colapsarse completamente. Los resultados encontrados proporcionan otra solución alternativa al problema de sobre-fusión para los grupos de Hickson. Asimismo, se encuentra que la razón masa-luminosidad de los grupos de Hickson podría ser similar a la de cúmulos de galaxias, sugiriendo que ambos tienen aproximadamente la misma fracción de materia bariónica a masa total.

ABSTRACT

A series of \(N\)-body simulations aimed to study the dynamics of small groups of galaxies are presented. In particular, our results are compared with the dynamical properties of Hickson’s compact groups (HCG). ‘Maximum expansion’ and virial initial conditions are tested, and no primordial common dark halo is considered. The properties of small galaxy groups are very well reproduced, and those of Hickson’s groups are well reproduced by the most advanced stage of collapsing groups. We find no overmerging problem in our simulations. An important fraction of groups (\(\sim 40\%\)) initially in virial equilibrium can last for \(\sim 10\) Gyr without complete merging. These results provide an alternative solution to the overmerging expected in Hickson’s compact groups. Also, the mass-to-light ratio of HCG are probably similar to those found in clusters, suggesting that both kinds of systems have about the same fraction of baryonic to total mass.

Key Words: GALAXIES: INTERACTIONS - GALAXIES: KINEMATICS AND DYNAMICS - METHODS: NUMERICAL

1. INTRODUCTION

Small groups are the most common galaxy associations and contain about 50% of all galaxies in the universe (Huchra & Geller 1982; Nolthenius & White 1987). Important work has been done to compile catalogs with relevant kinematical data. Thus Nolthenius & White (1987) and Nolthenius (1993) found that small groups from the CfA catalog (hereafter NCfA) have the following median values: a one-dimensional velocity dispersion of \(\sigma \approx 116\) km s\(^{-1}\), a mean harmonic radius of \(R_H = 480\) kpc, a deprojected median radius of \(R_S = 720\) kpc and a crossing time of \(H_0\tau_c = 0.44\).\(^2\) Hereafter a Hubble constant of \(H_0 = 75\) km s\(^{-1}\)Mpc\(^{-1}\) is assumed. Gourgoulhon, Chamaraux & Fouqué (1992, hereafter GCF) found for nearby small groups (\(< 80\) Mpc) a median

\(^{1}\)E-mail: aceves@astrosen.unam.mx

\(^{2}\)Here, \(R_S \equiv 4R/\pi\), \(R_H^{-1} = 4\Sigma_i\Sigma_{ij} R_{ij}^{-1}/(\pi N g(N_g - 1))\), and \(\tau_c \equiv 2R_H/(\sqrt{3}\sigma)\), where \(R\), \(R_{ij}\) and \(N_g\) are the average projected separation, the projected separation between galaxy pairs and the number of galaxies, respectively.
$\sigma \approx 75 \text{ km s}^{-1}$, a virial radius of about 770 kpc and a crossing time-scale of $\sim 4$ Gyr, these quantities corrected for the effect of the Hubble flow. More recently, Makarov & Karachentsev (2000, hereafter MK) derived from a sample of 839 groups, in particular for those consisting of five galaxies, the following mean values, with quartiles: $\sigma = 57^{+26}_{-14}$ km s$^{-1}$, a non-deprojected harmonic radius of $230^{+92}_{-59}$ kpc and a dimensionless crossing time of about 0.1.

A special and very important case is Hickson’s compact groups (HCG) which are characterized for being composed of at least four galaxies with a median projected separation of about three times the diameter of their luminous component and densities similar to the central region of rich clusters (Hickson 1982; Hickson 1997). Hickson’s initial catalog contained 100 groups with a median projected separation of $R = 52^{+80}_{-21}$ kpc, a velocity dispersion of $\sigma = 206^{+117}_{-71}$ km s$^{-1}$ and a dimensionless crossing time of $H_0 t_c = 0.016^{+0.007}_{-0.001}$; where $t_c = 4R/(\pi \sqrt{3}\sigma)$, and subscripts and superscripts indicate the range of observed values. However, Sulentic (1997) pointed out that only 61 of them show according redshifts.

It is noteworthy that HCG provide an ideal site to study the evolution of galaxies, via interactions and/or mergers, in a high density environment. One of the most striking challenges of the compact groups is how to reconcile their apparent longevity with their quite small crossing time of about 1% of the Hubble time. This short time-scale suggests a rapid evolution of these systems toward a complete merging within a Hubble time. This result was also corroborated by Bode, Cohen and Lugger (1993). And, (2), groups whose initial conditions begin in ‘turnaround’ or ‘expansion’ merge more rapidly than their virialized counterparts.

More recently, Athanassoula et al. (1997) carried out a more systematic study of the parameter space for small groups (e.g. concentrations of the common and individual haloes, common-halo-mass to total-group-mass ratios, etc.). Their main findings are: (1) centrally concentrated groups merge faster for high common-halo to total-mass ratios and slower for low common-halo to total-mass ratios. (2) The overmerging issue of compact groups may not be a problem if appropriate initial conditions are chosen. To support this last point, they built up a virialized group with a large common-halo to total-group and an almost homogeneous central concentration that was able to survive for as long as $\sim 20$ Gyr. According to these results the merger rates obtained from group simulations without including a common envelope, as the ones to be considered here, would be an upper limit.

In this work the hypothesis of Barnes (1989) and White (1990) regarding that diffuse groups might be the progenitors of compact ones, but criticized by Diaferio et al. (1994) for lacking quantitative support, is tested; similarly, the hypothesis advanced by Diaferio, Geller & Ramella 1994; Governato, Tozzi & Cavaliere 1996). Diaferio et al. (1994) introduced a scenario where a continuous replenishment of the compact group occurs within a single collapsing rich loose group. Governato et al. (1996) proposed an alternative model that relies in the evolution of a compact group as an ongoing and frequent process through secondary infall of galaxies in a critical universe. However, in these scenarios merging is not suppressed so one would expect more compact groups and merger remnants than those observed today (Mamon 2000).

On the other hand, there is a dynamical view where some kind of tuning of the initial conditions is imposed in order to guarantee the survival of the compact group. In this sense, Barnes (1985) was the first to investigate the effects of different kinds of initial conditions on the evolution of compact groups. He found that (1) a compact group immersed in a massive common halo would, in general, delay its merging process if more mass is initially placed in this common halo. This merging delay results from the fact that the halo common mass is obtained from the galaxy haloes, thus reducing their masses and increasing the dynamical friction time-scale. This result was also corroborated by Bode, Cohen and Lugger (1993). And, (2), groups whose initial conditions begin in ‘turnaround’ or ‘expansion’ merge more rapidly than their virialized counterparts.

In section §2 the numerical methods to set up the galaxy models and the initial condition for the group are described. In section §3 the merging histories of our simulations are performed without including a common halo. These simulations allow us to compare with the observed kinematical properties of small groups. The rest of this paper has been organized as follows: in section §2 the numerical methods to set up the galaxy models and the initial condition for the group are described. In section §3 the merging histories of our simulations and the dynamical properties are given in section §4. In section §5 the mass estimation of our
groups is addressed. A constrained representation of the ‘phase-space’ is shown in section §6. A more realistic N-body simulation involving spiral galaxies is given in section §7, and section §8 contains a general discussion of the results. Finally, the main conclusions are summarized in section §9.

2. DESCRIPTION OF THE SIMULATIONS

This section contains a detailed description about the method used to set up our galaxy model and the initial conditions for our small galaxy groups. Also, the computational tools and the parameters used to evolve our simulations are described.

2.1. Galaxy Model

Individual galaxies are represented by a self-consistent Plummer model. In building up the galaxy model no explicit difference between dark and luminous matter is done. However, to gain some feeling about the evolution of a luminous component, the initial 10% of most bounded particles are identified as ‘luminous’.

By using the procedure described by Aarseth, Hénon and Wielen (1974), positions and velocities of the particles are randomly generated from the following mass and phase-space distributions \( f(E) \):

\[
M(r) = M_g \frac{(r/R_0)^3}{[1 + (r/R_0)^2]^{3/2}}
\]

and

\[
f(E) = \frac{24\sqrt{2}R_0^3}{7\pi G^2 M_g^4} |E|^{7/2},
\]

where \( M_g \) is the total galaxy mass, \( R_0 \) its scale-length, and \( E \) the energy per unit mass, respectively.

A system of model units such that \( G = 1, M_g = 1 \) and \( R_0 = 1 \) is chosen. Since at large radii the Plummer density goes as \( \rho \propto r^{-5} \) a cut-off radius is introduced, for numerical purposes, at about \( r_{\text{cut}} \approx 10 R_0 \) which contains about 99% of the total galaxy mass. In this system of units, the dynamical time-scale, the half-mass and the cut-off radii are given by \( t_d = \sqrt{8R_0^3/(GM_g)} = \sqrt{8}, R_h \approx 1.3 \) and \( r_{\text{cut}} = 10 \), respectively. In order to compare with observational data the values \( r_{\text{cut}} \approx 135 \) kpc and \( M_g \approx 5.5 \times 10^{11} \) \( M_\odot \) (Model B of Kuijken & Dubinski (1995)) are adopted. For these values the time and velocity units are 31.5 Myr and 419 km s\(^{-1}\). In general, the simulations can be easily scaled through the following expressions for the velocity and time: \( v = 2.1 \times 10^{-3} \sqrt{M_g/R_0} \) km s\(^{-1}\) and \( t = 4.7 \times 10^3 \sqrt{R_0^3/M_g} \) Myr, where \( R_0 \) and \( M_g \) must be given in kpc and \( M_\odot \), respectively. With these definitions our initial ‘luminous’ core is contained within a radius of 0.74 model units, \( \approx 10 \) kpc. Finally, each galaxy is represented by 3000 equal-mass particles.

2.2. Group Initial Conditions

In all cases each group consists of five equal-mass galaxies. Galaxies are assumed to be already formed and no secondary infall is considered, which is justifiable in a low density universe (e.g. Bahcall 1999, Hradecky et al. 2000). The positions and velocities for the center of mass of these galaxies are randomly generated from initial conditions starting at ‘turnaround’ and at virial equilibrium. In all simulations no primordial common dark halo is included. Although this assumption seems to contradict current cosmological models of structure formation, some observations on clusters and groups suggest that most of the dark matter is associated with the individual dark haloes of galaxies (e.g. Bahcall, Lubin & Droman 1995, Puche & Carignan 1991). Hence, the merging activity observed in our simulations could be an upper limit.

2.2.1. Collapsing groups

For groups initially in ‘turnaround’ the positions for the centers of galaxies were obtained randomly from an homogeneous sphere of radius \( R_{\text{max}} \) defined by (Gunn & Gott 1972, ignoring any contribution from the cosmological constant) \( R_{\text{max}} = (8GM_g t^2/\pi^2)^{1/3} \), where \( M_g \) represents the mass of the group enclosed within this radius at time \( t \); mass conservation will be assumed. Compact groups are assumed to be at the verge of complete collapse at the present epoch (e.g. Hickson et al. 1984, Rubin et al. 1991), then their collapsing time-scale \( t_{\text{clps}} \) turns to be the age of the universe \( t_0 \). Hence, \( R_{\text{max}} \) was evaluated at \( t_0/2 \) (Gott & Rees 1975).

For \( \Omega_0 = 1 \) it is found that \( t_0 = 2H_0^{-1}/3 \), and for \( \Omega_0 \rightarrow 0 \) that \( t_0 \approx H_0^{-1}(1+0.5\Omega_0 \ln \Omega_0) \) (Gott et al. 1974).\(^3\) In particular for \( \Omega_0 = 0.2 \) and \( H_0 = 75 \) km s\(^{-1}\)Mpc\(^{-1}\) \( t_0 \approx 10 \) Gyr the ‘turnaround’ epoch was 5 Gyr ago (i.e. at redshift \( z \approx 0.6 \), Sandage 1961). In Table 1 the ‘turnaround’ radius of the group is listed for different values of \( H_0 \) and \( \Omega_0 \). A \( R_{\text{max}} = 700 \) kpc is taken as the fiducial ‘turnaround’ radius for collapsing groups. Notice that this value is consistent with a \( H_0 = 50 \) km s\(^{-1}\)Mpc\(^{-1}\) and \( \Omega_0 = 1 \), and with the observational data of Sulentic (1987) who found that there is not a significant population

---

\(^3\)This approximation differs by less than 1% from its true value for \( \Omega_0 = 0.2 \) (Peacock 1999).
of normal galaxies within $\sim 1$ Mpc of the central region of HCG.

Finally, the bulk velocity magnitudes for the galaxy centers were obtained randomly from a Gaussian distribution with a one-dimensional velocity dispersion of $\sigma = \sqrt{4GM_G/(5R_{max})}$ (Gott 1975) subject to the constrain $2T/|W| = 1/4$ (Barnes 1985), where $T$ and $W$ are the kinetic and potential energy of the group, respectively; these energies were computed assuming that galaxies are equal point-mass particles. Velocity vectors were oriented randomly.

2.2.2. Virialized groups

Theoretical arguments and $N$-body simulations (Peacock 1999) indicate that by a time $\approx 3t_{clps}/2$ a system has reached an approximate equilibrium state with a virial radial scale of $R_v \approx R_{max}/2$. Hence a radial scale for groups in near virial equilibrium at $t_0$ is $R_v = R(3t_0/2)/2$, and in the particular case for our fiducial model $R_v = 267$ kpc is obtained. The positions for the galaxies are randomly chosen from a uniform spherical distribution with radius $R_v$, and their velocities from a Gaussian distribution restricted to satisfy the virial ratio $2T/|W| = 1$ with random orientation vectors.

2.3. Computational Issues

To evolve our galaxy and group models a serial TREECODE was used (Barnes & Hut 1986) with a tolerance parameter $\theta = 0.9$ and with the quadrupole corrections to the potential included. A softening parameter $\epsilon = 0.07 \approx R_0/14$ and a time-step $\Delta t = 0.1$ were adopted. With these parameters, the simulations were evolved for about 321.4 time units ($\sim 10$ Gyr) and the energy conservation, in all cases, was better than 0.7%. A total set of 30 simulations were performed for each kind of initial conditions considered for the groups.

To follow up the orbital evolution of each galaxy inside the group its center was identified with its most bounded particle, which was set by ‘hand’ to have 1% of the galaxy mass (Aguilar & White 1985). In order to check the stability of the galaxy model due to this change its evolution was followed, in isolation, for $\sim 200$ dynamical time-scales, no significant change in its inner structure and in the total energy conservation was found. From here on, all kinematical properties of the group simulations (e.g. mean separation, velocity dispersion, etc.) will be obtained from these galaxy centers.

3. MERGING HISTORIES

In this section the merging histories for all our simulations of small groups are computed. These histories provide some insight about the merging rate and the overmerging problem of compact groups posed by their small crossing time.

In Figure 1 the evolution of three particular simulations with cold initial conditions is shown. Notice that group $g27c$ does not present any merger during the simulation ($\sim 10$ Gyr) while group $g02c$ completely merged. At present epoch (i.e. $\sim 5$ Gyr from ‘turnaround’), group $g22c$ resembles a chain-like compact group which is better appreciated at the bottom-right of this figure where only ‘luminous’ particles have been displayed. Notice also that groups $g27c$ and $g02c$ may be classified as triplets.

In order to characterize this merging activity the following pair-wise merging criteria (Aarseth & Fall 1980) are employed:

$$V_{ij} = |v_j - v_i| < V_{rms}/2, \quad R_{ij} = |r_j - r_i| < R_0/2;$$

where $V_{ij}$ and $R_{ij}$ are the relative velocity and separation between a pair of galaxies $i$ and $j$, respectively, and $V_{rms}$ and $R_0$ are their characteristic internal velocity and radius.

In Figures 2 and 3 the time evolution of the merging activity in our groups is shown. The dynamical time for the virialized groups is $t_d = \sqrt{8R_0^3/(GM_G)} \approx 111$ corresponding to about 3.6 Gyr. It is observed in Fig. 2 that no group has merged completely at the present epoch, $t_0$, although some multiple mergers do exist. About 15 groups (50%) do not present any merger at all, 9 (30%) show a merger of two galaxies and 6 (20%) triple or quadruple mergers. Notice that at the end of the simulations just one group does not show any merger and 15 (50%) have merged completely.

In the case of virialized groups, 5 ($\approx 17\%$) do not present any kind of merging within a dynamical time-scale, 11 ($\approx 37\%$) show a merger of two galaxies, 10 ($\approx 33\%$) have triple or quadruple mergers.
Fig. 1. This figure shows the XY-projection in kpc for the collapsing groups $g27c$ (upper-left), $g02c$ (upper-right) and $g22c$ (bottom-left). The numbers in each frame indicate the time elapsed since turnaround in Gyr. Lines refer to the trajectories followed by each galaxy inside its corresponding group. Also, small boxes of 300 kpc wide are shown at time 4.79 Gyr for each group. These boxes have been amplified and show just 'luminous' particles at the bottom-right of this figure which corresponds to the XY, XZ and YZ-projections.

Fig. 2. Number of individual galaxies versus time (merging history) for simulations with cold initial conditions. The free-fall time-scale (Mamon 1990) $t_{ff} = \pi \sqrt{R_{max}^3 / (32GMG)}$ and the present epoch $t_0 (\sim 5$ Gyr from 'turnaround') are indicated by arrows. The merging tracks have been displaced vertically and in time for better appreciation. The displacement in time corresponds to 0, 3, 6, 9 and 12 time units. A scale corresponding to 1 Gyr is indicated.

Fig. 3. As in Fig. 2, but for initially virialised groups. In this case, the arrow corresponds to the dynamical time of the group.
and only 4 (≈ 13%) have completely merged (see figure 3). Notice that about 12 (40%) have not completely merged after ~ 10 Gyr of evolution. This clearly indicates that some compact groups can survive complete merging for about a Hubble time.

4. DYNAMICAL PROPERTIES

The dynamical properties of the groups along three orthogonal ‘lines-of-sight’ at different times are determined. The median values for the one-dimensional velocity dispersion, the mean harmonic and deprojected radii, the VME and MME masses (see §5), and the dimensionless crossing time, \( H_0 \tau_c \), and the dimensionless crossing time as in Hickson et al. (1992), \( t_c \), are summarized in Table 2. The times indicated in the table correspond to 0.5, 1, 2, ..., 10 Gyr of evolution from their respective initial conditions.

4.1. Collapsing Groups

In Figure 4 the dynamical parameters as a function of time for our collapsing groups \( g27c \), \( g02c \) and \( g22c \) are shown, respectively. For comparison purposes the medians of MK and HCG are indicated by arrows. This figure shows the general trend in a collapse; a decrease in size followed by an increase in velocity dispersion and a reduction in the crossing time. The size of a group depends on the method adopted; the harmonic radius is always lower than the mean separation radius and, hence, \( \tau_c < t_c \). An agreement between both definitions of crossing times occurs when the systems are still rather diffuse. This is due to the fact that the harmonic radius \( R_H \) is more sensitive to smaller separations than \( R_S \).

The kinematical properties of \( g27c \) and \( g02c \) at the present epoch are in good agreement with the values found in NCfA, GCF, and MK groups. In general, our simulations reproduce very well the kinematical parameters of ‘normal’ small groups of galaxies (see Table 2).

**Group \( g27c \).** This group has properties at the present epoch that resemble those of a ‘normal’ diffuse group: \( R_H \approx R_S \approx 700 \text{ kpc}, \sigma \approx 70 \text{ km s}^{-1} \), and \( H_0 \tau_c \approx H_0 t_c \approx 0.5 \). These values are large with respect the observed ones in HCG, but in better agreement with the medians of NCfA, GCF, and MK groups.

**Group \( g02c \).** This system has a similarity with Hickson’s groups; it shows a \( \sigma \approx 200 \text{ km s}^{-1} \) and \( H_0 t_c \approx 0.09 \) when is observed along the Y-axis (see Fig. 4). However, its mean separation is quite large \( R_S \approx 400 \text{ kpc} \). The average values, over the three lines of sight, obtained at the present epoch are:

\[
R_H \approx 10 \text{ kpc}, \quad R_S \approx 250 \text{ kpc}, \quad \sigma \approx 90 \text{ km s}^{-1}, \quad H_0 \tau_c \approx 0.01, \quad \text{and} \quad H_0 t_c \approx 0.2.
\]

**Group \( g22c \).** This group has dynamical properties, at the present epoch, that resemble very closely the medians of Hickson’s groups: \( R_H \approx 40 \text{ kpc}, \quad R_S \approx 110 \text{ kpc}, \quad \sigma \approx 120 \text{ km s}^{-1}, \quad H_0 \tau_c \approx 0.1, \quad \text{and} \quad H_0 t_c \approx 0.05 \). However, a \( R_S \approx 50 \text{ kpc} \), \( \sigma \approx 180 \text{ km s}^{-1} \) and \( H_0 t_c \approx 0.01 \) are found along the Z-axis. We should mention that the selection of \( g22c \) was based solely on its similarity with HCG at the present time when seen in the XY-plane, which is confirmed with the more realistic models of spiral galaxies in section §6. In this group, the three closest galaxies merge in ~ 1 Gyr from the present epoch, while the other two form a wide ‘binary’ at the end of the simulation (10 Gyr). This result suggests that although some HCG have small crossing times they will not merge completely over several Gyr from the present epoch.

Histograms for the dynamical properties of collapsing groups at times \( t \approx 0.5, 3, 5 \text{ Gyr} \), normalized to the initial number of ‘observed’ groups, are shown...
in Figure 5. The median values obtained by different authors are also indicated. The crossing time as defined by Hickson et al. (1992) is shown in the left-panel of Figure 6.

This ensemble of simulations shows a general trend to lower their size and increase their velocity dispersion, until the point where ‘binaries’ or ‘triplets’ start to form. At this stage the velocity dispersion of the group begins to decrease due to the transfer of orbital energy to the internal degrees of the individual galaxies. Also, the harmonic radius distribution shows a strong increase in its lower end while the velocity distribution increases its higher end (see Fig. 5). Notice that at the present epoch ($t \approx 5$ Gyr) there is a significant fraction of groups with $\sigma \gtrsim 100$ km s$^{-1}$.

It is important to point out that the median values observed in catalogs of ‘normal’ small groups are well reproduced by our collapsing groups at the present epoch (e.g. $\sigma$ and $R_S$ in Figure 5). About 30% of the collapsing groups have a $\sigma$ value close to the median of HCG and $\approx 50\%$ have a similar $R_S$. Furthermore, the majority of the crossing times fall within the values found in HCG (Figure 6) and $\approx 50\%$ would be classified to be virialized at the present epoch accordingly with the criterion of Gott & Turner (1977).

Hickson’s catalog (Hickson 1982, Hickson et al. 1992) has 16 groups with $\sigma \lesssim 100$ km s$^{-1}$ and just five of them show a $\sigma \lesssim 5$ km s$^{-1}$. Four of these last groups (HCG38, HCG47, HCG49 and HCG88) have a dimensionless crossing time of $H_0 t_\tau \gtrsim 1$ suggesting they are not close to virial equilibrium. However, our results indicates that such a assumption may not be correct.

Since our models roughly agree with those HCG exhibiting a low velocity dispersion, they suggest a probable explanation for that fact (Rubin et al. 1991, Mamon 2000).

4.2. Virialized Groups

Figure 7 contains histograms for the dynamical quantities for virialized initial conditions at times $t \approx 0.5, 3.6$ Gyr. According with Table 2, these groups present a median of $\sigma \approx 90$ km s$^{-1}$, $R_H \approx 200$ kpc, $R_S \approx 250$ kpc, $H_0 \tau_c \approx 0.20$ and $H_0 t_\tau \approx 0.13$ at their initial stages. After 5 Gyr of evolution the following medians are obtained: $\sigma \approx 58$ km s$^{-1}$, $R_H \approx 6$ kpc, $R_S \approx 274$ kpc, $H_0 \tau_c \approx 0.01$ and $H_0 t_\tau \approx 0.21$ which are far from the values found in Hickson’s groups.

In general, the $\sigma$-distribution shows small changes even after $\sim 10$ Gyr of evolution; however,
Fig. 4. Kinematical parameters as a function of time for collapsing groups $g27$, $g02c$, and $g22c$. Astronomical units are used. The left-arrow ($\leftarrow$) indicates the median of the 5-galaxy MK groups, while the right-arrow ($\rightarrow$), HCG. The different lines indicate the line-of-sight used to compute the quantities: along X-axis (solid), along Y-axis (dotted), and along Z-axis (broken). For the dimensionless crossing times, thicker lines for $H_0\tau_c$ than for $H_0t_c$ have been used.

The $R_H$-distribution presents significant changes which are also observed in the evolution of the $H_0\tau_c$-distribution. The $\sigma$-distribution tends to populate the regions of lower velocity dispersion and to increase somewhat the mean separation. Notice that about 50% of groups have at $t = 0$ crossing times similar to those of normal small groups (NCIA, GCF, and MK) and $\sim 5\%$ close to the median of Hickson’s groups.

The results of this and the previous sections indicate that a large fraction ($\sim 40\%$) of our initially virialized groups have not merged during 10 Gyr and, hence, the overmerging (Hickson 1997) may not be a problem. However, it is important to point out that in our simulations a primordial common dark halo has not been included, which may change our conclusions.
Fig. 6. Evolution of the distribution of the crossing-time $t_c = R_S/\langle \sqrt{3}\sigma \rangle$. Lines styles are the same as in Fig. 5. The interval of crossing-times for HCG and that assumed to be satisfied by virialized groups, according the criterion of Gott & Turner (1977), are indicated. The left panel shows results for collapsing groups, while the right one for virialized. Notice that both kinds of initial conditions lead to ranges in crossing-time within the observed values.
velocities, along the line-of-sight with respect to the centroid of $M$ and the constant in $g$ function of time for our collapsing groups (Aceves & Perea 1999 and references therein): Tremaine & Bahcall 1985, Aceves & Perea 1999 and estimators are defined, respectively, as (Heisler, 1984) a lower fractional limit on the virial mass is $\delta \sqrt{\frac{2\pi N}{(\pi^2 \sqrt{N})}}$, leading to $M_v \approx 1.28 \pm 0.12$ for $N = 90$ 'observed' groups.

The results from all the simulations carried out are summarized in the histograms of Figure 9. The true mass of the groups is indicated by the vertical line. For collapsing groups (left panels) the VME estimator (left-upper panel) gives a median virial mass of $M_v = 1.28$ at $t = 15$ which is consistent with the expected value of $M_v = 1.25$, while the MME (left-lower panel) underestimates the mass by about an order of magnitude. However, once the groups are allowed to evolve to the present epoch ($\sim 5$ Gyr) the mass is underestimated by an order of magnitude for the VME and by a factor of about 5 for the MME method. For the case of virialized groups we found that at $t = 0$ both mass estimators give a similar median mass of about $M_v \approx 3.5$. Once the separation between galaxies decreases, the MME provides a better estimate of the mass. From these results, the MME is considered more appropriate to estimate the mass of systems that resemble HCG.

Hickson’s compact groups have a mass-to-light ratio of $\Upsilon \approx 50 h \Upsilon_\odot$. If HCG are physically well defined groups, their content of matter is probably $\gtrsim 5$ times more than is inferred now. This would imply that a closer estimate to the true mass-to-light ratio of HCG would be $\Upsilon \sim 250 h \Upsilon_\odot$. It is interesting to note that this value falls within the values found in clusters $200 - 300 h \Upsilon_\odot$ (Bahcall 1999) suggesting that both types of systems would have approximately the same fraction of baryonic to dark matter (see White et al. 1993 for a discussion of the cosmological implications).

6. $R_S-\sigma$ DIAGRAM

A restricted ‘phase-space’ consisting of a $R_S-\sigma$ diagram is constructed in order to try to discern some evolutionary track in our simulated groups. In Figure 10 the collapsing (left-panel) and virialized (center-panel) groups are shown at times $t = 0.5$ and $t = 5$ Gyr together with the corresponding diagram for HCG where the ones considered ‘bona fide’ by Sulentic (1997) are indicated.

This diagram clearly shows that initially cold groups reduce their mean separation and increase...
Fig. 8. Time behavior of the two mass estimators considered in §5 for our collapsing groups $g27c$, $g02c$ and $g22c$. The upper panels show the virial mass while the bottom the median mass. The horizontal broken line corresponds to the total mass of the groups; $N$-body units are used for the mass while physical units for the time. The different types of line denote different lines-of-sight as in Figure 4.
Fig. 9. Histograms of the behavior of the VME (upper panels) and MME (lower panels), both for cold (left) and virial (right) small groups. The bar (|) indicates the true mass of the groups in N-body units. Dotted lines show the distribution at $t = 0.5$ Gyr, short-dashed lines at 3 Gyr and solid at 5 Gyr.
their velocity dispersion as they evolve, while for virialized groups their velocity dispersions decrease somewhat and their mean separation tends to increase. Furthermore, about 8 collapsing groups have $R_S \lesssim 100$ kpc and $\sigma \in (60, 200)$ km s$^{-1}$ at the present epoch ($\sim 5$ Gyr) which roughly correspond to the values shown by ‘normal’ small groups, and are within the range of values found for HCG. Also, 2 groups have $R_S \lesssim 50$ kpc and $\sigma \approx 200$ km s$^{-1}$ which are very close to the median values of HCG.

This $R_S-\sigma$ diagram suggests a resemblance of HCG with our the systems that once had a diffuse configuration and are at the verge of collapse at the present time, while some of our virialized groups show properties more similar to the ‘normal’ small groups. These and previous results suggest that HCG are the more advanced systems in a process of gravitational collapse among small groups. Thus, compact groups may be rather young configurations (Hickson et al. 1984, Barnes 1989, White 1990, Rubin et al. 1991).

7. A MORE REALISTIC SIMULATION

In the simulations reported above no clear distinction between luminous and dark matter was made, and hence no precise statement could be established whether, for example, the group $g_{22c}$ could actually be considered a compact group according to Hickson’s criteria.

To address this particular issue a more realistic galaxy model was set up by replacing the plummer models by spiral galaxies using model B of Kuijken & Dubinski (1995); see §2.1 for some numerical values of this model (we refer the reader to Kuijken & Dubinski’s paper for a detailed description of the method to build up the disk galaxy model). It should be mention that a detailed study of groups involving disk galaxies is out the scope of the present work. Table 3 summarizes the parameters that define our galaxy model and Figure 11 shows its corresponding rotation curve.

For the galaxy centers and bulk motions inside the group the values of our previous collapsing model $g_{22c}$ are used. For illustrative purposes, arbitrary orientations for the galaxy angular momentum vector are chosen. Each numerical galaxy consists of 65536 particles, 16384 for the disk, 4096 for the bulge and 45056 for the halo; i.e., a total of 327680 were used in this simulation.

To evolve the system a parallel treecode developed by Dubinski (1996) with a tolerance parameter of 0.8 was used. Forces were computed with the quadrupole terms included and with a fixed time-step corresponding to 1 Myr. With these parameters the energy conservation was better than 0.2%. The simulation was ran in a Beowulf class cluster consisting of 32 Pentium processors of 450 MHz (Velázquez & Aguilar 2002). It took a wall time of 16 seconds per time-step.

In Figure 12 (left) the XY-projection of the luminous component of the group at time 4.8 Gyr, the same as figure 1 of model $g_{22c}$, is shown. Although differences in the evolutionary trend of our more realistic model are appreciated with respect to model $g_{22c}$, it is rather easy to conclude that it satisfies Hickson’s criteria for compact groups. Hickson’s criterion on the difference of magnitudes among galaxies is satisfied immediately since our galaxies are identical. Therefore, a group is obtained that is compact at the present epoch and will not merge completely for another $\sim 5$ Gyr.

In Figure 12 (right) only the dark particles of the haloes are shown. Notice that a common dark halo has already formed for three of the galaxies that will merge in the next few Gyr. This result is consistent with the suggestion by Rubin et al. (1991) that compact groups reside in a common dark halo at the present epoch.

8. GENERAL DISCUSSION

It has been found that $\approx 10\%$ of initially diffuse groups reach the present epoch with dynamical properties consistent with the median of Hickson’s compact groups. Hickson’s groups appear as those systems that have manage to evolve more rapidly toward a compact configuration, due to particular
Fig. 10. $R_s$-σ diagram for collapsing (left), virialized (center), and Hickson's groups (right). Hickson's compact groups appear to resemble systems that have suffered a gravitational collapse out of a more diffuse system.

Fig. 12. (left) XY-projection at time 4.8 Gyr of our more realistic model. Luminous particles are shown in the left-panel and the dark component is indicated in the right-panel. Notice that a common dark envelope for the three galaxies close to merging is already present, while the other two in the upper-left will not merge for $\gtrsim 5$ Gyr from the present epoch. Compare with our previous model $g22c$ of Figure 1.
initial conditions in the density perturbation that led to the formation of small groups. The formation of a compact groups is, according to our results, consistent with a hierarchical clustering scenario for the formation of structures in the universe. Hence supporting the hypothesis advanced by Barnes (1989) and White (1990), and the one suggested on observational grounds (Hickson et al. 1984, Rubin et al. 1991).

The present model leads to ~ 50% of originally diffuse groups arriving at the present epoch without any merging. Also, it is found that ~ 10% (5 simulations) of these groups will not have any merger within the next ~ 5 Gyr. In this sense, our model provides an alternative explanation to the properties of compact groups and their existence today, and complements several previous studies (e.g., Athanassoula et al. 1997).

In general, initial conditions from ‘maximum expansion’ reproduce very well the properties of ‘normal’ small groups. Our simple model avoids the requirement for an initial overdensity and/or significant secondary-infall (Diaferio et al. 1994, Governato et al. 1996), and the need for especial initial conditions to avoid the complete merging of a group (e.g., Athanassoula et al. 1997).

The present model does not show the merging instability, but many questions remain. One of the most obvious caveats of our simulations is not taking into account a primordial dark halo for virialized initial conditions. However, the merging activity found may still be considered a lower limit if a concentrated dark halo were to be included. Surely more realistic simulations of small groups, considering a spectrum of masses and a clear distinction between luminous and dark matter, as well as initial conditions taken from a cosmological simulation, are necessary to address these issues. We plan to study some of these matters in the future.

9. CONCLUSIONS

The main results of this work are as follows:

1. Groups starting from ‘maximum expansion’ with a diffuse configuration have, at the present epoch, dynamical properties very similar to the medians obtained from several catalogs of small groups. In particular, about 10% of them show values close to the observed medians of Hickson’s groups.

2. The suggestion that Hickson’s compacts groups originated from diffuse systems, and are relatively young systems, finds quantitative support in our numerical experiments.

3. It is found that overmerging is not an important problem in our simulations, either with virialized or cold initial conditions. For the case of virialized groups about 40% survive merging during ≈ 10 Gyr. This also indicates that the existence of a large, massive common dark halo does not appear to be a strong requirement to explain the present day properties of small groups.

4. The median mass estimator (MME) appears to be a better estimator of mass than the virial mass estimator (VME) for groups at the present epoch. It is estimated that the mass-to-light ratio of HCG is probably \( \Upsilon \sim 250\Upsilon_\odot \) suggesting that clusters and compact groups have about the same fraction of baryonic to dark matter.

Acknowledgments

H.A. thanks CONACyT (México, Proyecto:37506-E) and the Spanish Ministry of Foreign Affairs for financial support. H.A. thanks greatly Gary Mamon, Jack Sulentic, Lourdes Verdes-Montenegro, and Jaime Perea for important input on this work, and P. Hickson and P. Fouqué for sending their groups’ catalogs. H.V. was supported...
by a grant from CONACyT (Proyecto:27678-E). We thank W. J. Schuster for a careful reading of the final manuscript. Finally, we thank the anonymous referee for suggestions to improve and clarify this work.
