Aims

The association of body weight and weight change with mortality and cardiovascular (CV) outcome in patients with diabetes mellitus (DM) is not clearly established. We assessed the relationship between weight, weight change, and outcomes in patients with established CV risk factors and type 2 DM or pre-diabetes.

Methods and results

A total of 12,521 participants from the ORIGIN trial were grouped in BMI categories of low body weight [body mass index (BMI) < 22 kg/m²] normal (22–24.9), overweight (25–29.9), obesity Grades 1–3 (30–34.9, 35–39.9, >40 kg/m², respectively). Outcome variables included total and CV mortality and composite outcomes of CV death, non-fatal stroke, or myocardial infarction plus revascularization or heart failure hospitalization. Follow-up was 6.2 years (interquartile range 5.8–6.7 years). After multivariable adjustment, lowest risks were seen in patients with overweight and mild obesity for total mortality [overweight: hazard ratio (HR) 0.80 (95% confidence interval (CI) 0.69–0.91); obesity Grade 1: HR 0.82 (0.71–0.95), both P < 0.01] and CV mortality [overweight: HR 0.79 (0.66–0.94); obesity Grade 1: 0.79 (0.65–0.95), all compared to patients with normal BMI, P < 0.05]. Obesity of any severity was not associated with higher mortality. Low body weight was related to higher mortality [HR 1.28 (1.02–1.61); CV mortality: HR 1.34 (1.01–1.79), P < 0.05]. A continued 2-year weight loss was associated with higher risk of mortality [HR 1.32 (1.18–1.46), P < 0.0001 and CV mortality [HR 1.18 (1.02–1.35), compared to patients without weight loss, P < 0.05]. In turn, weight gain was not related to any adverse outcome.

Conclusion

Obesity in patients with DM or pre-diabetes and CV risk profile was not associated with higher mortality or adverse CV outcome. The lowest mortality risk was seen in patients with overweight and moderate obesity (BMI 25–35 kg/m²). Weight loss was an independent risk factor for higher mortality compared to no weight loss.

Keywords: Diabetes mellitus • Body weight • Weight change • Outcome • Risk factor • Obesity paradigm

Introduction

Overweight and obesity are established risk factors for cardiovascular (CV) disease 1–3, which is the leading cause of death in modern society. 4 Excessive body weight as a key component of the metabolic syndrome predisposes to insulin resistance and promotes development of type 2 diabetes mellitus (DM) which, too, is a risk factor for CV disease. Weight control is therefore widely promoted as a major...
preventive measure to reduce the burden of diabetes and subsequent CV disease. In accord with this concept, current guidelines for prevention and treatment of DM⁴ and of CV disease⁵ recommend weight reduction irrespective of CV comorbidity to improve disease status and outcome.

The impact of obesity on mortality in patients with established type 2 DM or at high risk of DM and with a prevalent CV risk profile is, however, less clear. It appears that with increasing age the optimum (or ideal) body weight is shifting towards a higher body mass index (BMI) range compared to the WHO-defined ‘ideal BMI’ of 18.5–25 kg/m².⁷,⁸ Increasing evidence demonstrates a survival benefit with overweight and mild obesity in patients at risk or with established CV disease.⁹ Previous registry data suggest a survival benefit in overweight patients with DM without CV disease compared to normal weight.¹⁰ While most clinical data on body weight and outcome report on a single-time assessment of body weight, prospective evidence on weight change affecting outcome is limited and not supportive of a beneficial effect of weight reduction. The LOOK-AHEAD trial applied a comprehensive lifestyle intervention program to overweight patients with type 2 DM.¹¹ A reduction of body weight and of subsequent surrogate markers of the metabolic syndrome was indeed achieved. Yet, the study showed that this weight reduction did not improve any of the outcome variables on mortality or morbidity. A 19-year follow-up study of patients with intentional weight loss of the randomized clinical trial ‘Diabetes Care in General Practice’ (DCGP) showed that weight loss in obese patients regardless of intention did not improve outcome but was an independent risk factor for increased all-cause mortality.¹²

The LOOK-AHEAD trial included 5145 relatively healthy patients with DM (14% with CV comorbidity), and the DCGP study was a population based cohort study in 1381 patients with newly diagnosed type 2 DM and a moderate CV risk profile (26–30% macrovascular comorbidity). In contrast, the ORIGIN trial investigated 12 537 patients with type 2 DM or pre-diabetes with 100% prevalent CV risk factors.¹³ The aim of this analysis from the ORIGIN trial data is to assess the relationship between body weight, weight change, and CV outcome in this cohort at high risk of CV events.

**Methods**

Previous publications describe the design and the results of the ORIGIN trial (ClinicalTrials.gov number, NCT00069784, funded by Sanofi).¹³¹⁴ In this randomized, controlled trial, patients with CV risk factors and either pre-diabetes or type 2 DM were allocated to receive insulin therapy or standard care and to receive n-3 fatty acids or placebo in a 2 × 2 factorial design. A total of 12 537 participants were enrolled in 573 clinical sites in 40 countries. Mean follow-up was 6.2 years (interquartile range 5.8–6.7 years). Body weight and height were assessed at baseline and weight was assessed at 2-month and at yearly follow-up throughout the trial. The primary outcome was a composite endpoint of CV death, non-fatal myocardial infarction (MI), or non-fatal stroke. Further outcome measures were individual components of the primary endpoint, all-cause mortality, total stroke, and total MI. The ORIGIN trial complies with the Declaration of Helsinki and was approved by the Ethical Committee at each site and each participant provided written informed consent.

**Body weight and weight change assessment**

Body mass index was assessed as ratio of body weight and height squared and was categorized according to the WHO criteria as underweight (BMI < 18.5 kg/m²), normal weight (18.5–<25 kg/m²), overweight (25–<30 kg/m²), obesity Grade 1 (30–<35 kg/m²), Grade 2 (35–<40 kg/m²) and Grade 3 (≥40 kg/m²). Due to the low number of participants with a BMI below 18.5 kg/m², we expanded in this analyses the category of low body weight to all participants with a BMI below 22 kg/m². Accordingly and in line with accumulating epidemiologic evidence, we used as reference group (normal weight) patients with a BMI 22–<25 kg/m².¹³

Weight change was assessed as % weight change from baseline. Sustained weight gain was defined as continued weight gain of ≥1.0 kg/year over 2 years with no intervening weight loss of ≥0.5 kg. Sustained weight loss was assessed as continued weight loss of ≥1 kg/year over 2 years with no intervening weight gain of ≥0.5 kg.

**Outcomes**

The primary outcome for this analysis was all-cause mortality. We further investigated the two composite outcomes of the ORIGIN protocol comprising: (a) primary composite endpoint of first occurrence of CV death, non-fatal MI, or non-fatal stroke; and (b) expanded composite endpoint of first occurrence of these three outcomes or revascularization or hospitalization for heart failure (HF). Further analyses included individual components of these composites and further outcomes such as total MI and total stroke.

**Statistical analyses**

Data analysis followed a prospectively designed analysis plan and used SAS software (version 9.4 for Solaris). Clinical characteristics are presented as means (± standard deviation) for continuous variables and by frequency (percentage) for categorical variables.

For comparison of baseline characteristics between BMI groups, analysis of variance (ANOVA) for continuous variables and χ² test for categorical variables were used. Event rates between groups were analysed by adjusted Cox regression model. Time to event curves for BMI subgroups were constructed for outcome variables with the use of adjusted survival curves. Hazard ratios (HR) and 95% confidence intervals (95% CI) for each outcome according to BMI group were calculated using the BMI category 22–<25 kg/m² as reference in Cox regression models adjusted (a) for age and sex (minimum adjustment) and (b) for age, sex, smoking status, previous CV events, duration of DM, waist circumference, systolic blood pressure, medication with ACE or ARB, beta-blocker medication, statin, LDL level, HbA1c level, eGFR, allocation to treatment arm glargine, and allocation to treatment arm n-3 fatty acid (full adjustment model). Previous CV events were defined according to the ORIGIN protocol as a history of MI, stroke, or revascularization.¹⁴ Heart failure was an exclusion criterion for the trial. Weight change analyses were performed using a multivariate adjusted Cox models that included weight gain and weight loss as time varying variables. A nominal P-value of 0.05 was used to indicate statistical significance.

**Results**

A total of 12 521 participants with baseline BMI measurements (mean age 63.5 years, 35% female) were included in this analysis (99.9% of the total study population). During a median follow-up of 6.2 years (interquartile range 5.8–6.7 years), these individuals suffered 1910 deaths (15.3%) of which 1153 (9.2%) were CV deaths. Clinical
Table 1  Baseline characteristics of study participants according to body mass index categories

Values are n (%) or mean (SD), N* number of patients if missing data, P-values for Log-rank test between categories. *Newly diagnosed diabetes at baseline. Previous CV event is defined according to the ORIGIN protocol as previous myocardial infarction, stroke or revascularization [15].
characteristics and medications in BMI subgroups are shown in Table 1. Overweight and obese participants were younger, had a higher prevalence of hypertension, and a higher blood pressure and LDL cholesterol than the normal weight participants. Obese participants also had a lower prevalence of prior CV events than normal weight participants at the time of randomization. No linear trends across BMI categories were seen for smoking status, previously known type 2 DM, or newly diagnosed DM at baseline.

The distribution of BMI within the study population is shown in Figure 1. The majority of participants were overweight (40.3%) and mildly obese (28.8%) while only 12.5% had normal weight. Absolute event numbers for all outcomes and composite endpoints are shown in Table 2. For total mortality, CV mortality, and for the primary composite endpoint a consistent inverse relation of event rates and BMI categories was observed with lowest event rates in severely obese or obese Grade 2 (CV mortality) patients (all \(P<0.01\)).

Time to event curves for total mortality and for CV mortality as well as for primary composite endpoint are shown in Figure 2A–C.

Hazard ratios for outcomes in BMI subgroups after adjustment for age and sex and after full adjustment for all available covariables are

![Figure 1](image.png)

Full adjustment for age, sex, ever smoker, previous cardiovascular event, LDL, Hba1c, eGFR, allocation to glargine, allocation to omega 3 fatty acid, duration of DM, waist circumference, systolic blood pressure, ACE or ARB medication, beta-blocker medication, statin medication. Hip circumference, hypertension and diastolic blood pressure were not included in the model because of collinearity.

\(^a\)Primary composite endpoint: composite of first occurrence of cardiovascular death, non-fatal myocardial infarction, or non-fatal stroke.

\(^b\)Expanded composite endpoint: composite of first occurrence of these three outcomes or revascularization or heart failure hospitalization.
shown in Table 3. Adjusted risk models show that patients with overweight and with mild to moderate obesity have a significant lower risk of all-cause mortality, CV mortality, and for the primary composite endpoint compared to the reference group (Table 3 and Take home figure). Outcomes for non-fatal endpoints are shown in Supplementary material online, Table S1. None of the mortality endpoints or the composite outcomes showed a higher risk in CV outcomes with higher BMI. In contrast, patients with low body weight had a higher risk of all-cause mortality and of CV mortality (Table 3). A sensitivity analysis further subdivided the low BMI subgroup into tertiles and showed a heterogeneous distribution of outcome across tertiles. This suggests that the adverse outcomes in this subgroup were not driven exclusively by a subset of patients with extremely low BMI (Supplementary material online, Table S2).

**Weight change analyses**
Weight gain and weight loss (% of body weight) during the first year of follow-up was assessed in multivariable adjusted models (Table 4). Weight gain was related to lower mortality (all-cause and CV mortality) and to better outcome (composite outcomes, stroke, revascularization, or HF hospitalization) in comparison to patients with no weight gain. In contrast, weight loss was related to higher risk of death, and to worse outcome compared to patients with no weight loss.

Sustained weight gain over 2 years with no weight loss during these 2 years was observed in 2863 patients and sustained weight loss over 2 years was observed in 1755 patients. Sustained weight gain did not relate to a higher risk for any of the assessed outcome variables in comparison to patients without weight gain. In turn, sustained weight loss was related to worse outcome for all-cause mortality and for CV mortality (Table 5) compared to no weight loss. Patients who remained at stable weight had a better mortality outcome compared to patients with sustained loss or gain of body weight.

**Discussion**
The analysis showed that in patients with CV risk factors and with either type 2 DM or prediabetes, people who were overweight and mildly obese had a lower all-cause and CV mortality, as well as a fewer composite CV outcomes (non-fatal MI, non-fatal stroke, or CV death) than people whose BMI was 22–25 kg/m². It also showed higher mortality and CV outcomes in those patients with BMI below this threshold.

The relation of body weight and outcome is reported in most observational studies based on single-time assessment of body weight. Our study extends the present knowledge as we report on weight change in relation to outcome in these patients with DM or prediabetes. Weight loss but not weight gain was associated with worse outcomes compared to those with stable body weight. This is in line with recent data in patients with coronary artery disease, where fluctuation in body weight was associated with higher mortality and higher rate of CV events.

Our findings are in line with previous reports on an inverse relation of body weight and outcome across a wide range of CV disease settings and in multiple population-based cohort studies. This finding was initially termed ‘obesity paradox’ as it is counterintuitive to the setting of primary prevention where excessive body weight is clearly established as a risk factor for CV disease. The reproducibility of these findings and recent pathophysiologic insights that suggest a benefit of excessive energy stores in the context of disease related...
In patients with DM two meta-analyses including 18 longitudinal clinical trials and registries\textsuperscript{17} and 16 cohort studies\textsuperscript{18} report the lowest mortality in overweight and mildly obese patients. Registry data from 10 568 patients with DM and no CV disease\textsuperscript{19} and data from the DIAMOND prospective cohort registry in 1192 patients with DM after acute MI\textsuperscript{19} showed a lower all-cause mortality in overweight patients (BMI > 25 kg/m\textsuperscript{2}) compared to non-obese patients. A prospective cohort study including 11 449 Chinese adults with DM showed lowest mortality in obese patients and significantly lower risk of death in overweight patients compared to patients with normal weight.\textsuperscript{20}

Cardiovascular death is the most common cause of death in diabetic patients and the prevalent CV risk profile in the cohort of the ORIGIN study may contribute to explain the observed association of body weight and outcome in these patients. This is supported by a recent report on over 170 000 patients from 14 prospective studies.\textsuperscript{21}

All participants in the ORIGIN trial had a CV comorbidity. In contrast, in a recent study in patients with incident type 2 DM who were free

---

Weight gain, weight loss, and stable weight were treated as time varying covariables in multivariable adjusted models (Cox regression model adjusted for age, sex, ever smoker, previous cardiovascular event, LDL, HbA1c, eGFR, allocation to glargine, allocation to omega 3 fatty acid, duration of DM, waist circumference, systolic blood pressure, ACE or ARB medication, beta blocker medication, statin medication. Hip circumference, hypertension, and diastolic blood pressure were not included in the model because of collinearity.). HR’s compare the category vs. all subjects outside the category.

\textsuperscript{a}Primary composite endpoint: composite of first occurrence of cardiovascular death, non-fatal myocardial infarction, or non-fatal stroke.

\textsuperscript{b}Expanded composite endpoint: composite of first occurrence of these three outcomes or revascularization or heart failure hospitalization.

---

The DIAMOND prospective cohort registry in 1192 patients with type 2 DM and no CV disease\textsuperscript{16} and data from 14 cohort studies\textsuperscript{17} report the low-weight patients (BMI > 25 kg/m\textsuperscript{2}) compared to non-obese patients. A catabolic conditions led to challenge the terminology of a paradox (i.e. unexpected and unexplained).\textsuperscript{16}

In patients with DM two meta-analyses including 18 longitudinal clinical trials and registries\textsuperscript{17} and 16 cohort studies\textsuperscript{18} report the lowest mortality in overweight and mildly obese patients. Registry data from 10 568 patients with DM and no CV disease\textsuperscript{19} and data from the DIAMOND prospective cohort registry in 1192 patients with DM after acute MI\textsuperscript{19} showed a lower all-cause mortality in overweight patients (BMI > 25 kg/m\textsuperscript{2}) compared to non-obese patients. A prospective cohort study including 11 449 Chinese adults with DM showed lowest mortality in obese patients and significantly lower risk of death in overweight patients compared to patients with normal weight.\textsuperscript{20}
of CV disease, overweight, and obesity were not associated with improved outcome. In the latter study, self-reported measures were used to calculate BMI. Notably, a systematic bias in self-reported weight data has repeatedly been observed leading to overestimation of the association of obesity with worse outcome. The present study used measured values instead of self-reported date for the calculation of BMI thus avoiding the potential bias from self-reported BMI values.

Notably, in patients with DM a range of body weight at BMI near 30 kg/m² is the commonly observed average weight distribution. Hence, lower body weight may per se indicate some underlying problem associated with illness or metabolic imbalance which may contribute to explain the observed findings. Cancer related death is often discussed to account for higher mortality in underweight subject. In the ORIGIN cohort, however, the proportion of CV death was higher (64%) in the subgroup of low body weight as in all other BMI subgroups (Table 1). It was shown previously in the ORIGIN population that BMI was not different between patients with vs. without cancer (BMI 29.9 ± 4.8 vs. 29.8 ± 5.3 kg/m², P = 0.68) and that body weight was not associated with cancer mortality in multivariate analysis. Cancer mortality is therefore unlikely to account for the higher mortality rate in patients with low body weight in this cohort study. We cannot exclude that diseases which were not recorded in the ORIGIN dataset were more prevalent among patients with low body weight. However, a range of comorbidities and clinical variables with known impact on CV outcome were recorded and were included in our analyses (Table 1). Smoking is a commonly discussed factor to explain higher mortality among subjects with lower body weight. Smoking status was assessed in the ORIGIN study cohort, however, the proportion of CV death was higher (64%) in the subgroup of low body weight as in all other BMI subgroups (Table 2). It was shown previously in the ORIGIN population that mean BMI was not different between patients with vs. without cancer (BMI 29.9 ± 4.8 vs. 29.8 ± 5.3 kg/m², P = 0.68) and that body weight was not associated with cancer mortality in multivariate analysis.

Limitations

Our study is a post hoc analysis of a large clinical trial database and limitations of such analysis apply. Despite multivariate adjustments, some baseline differences may still be unaccounted for, thus definite conclusions may only be possible from a prospective randomized trial on weight management. From the observed associations, no causal interaction can be concluded. Our study cannot answer the question of potential benefits from intentional weight reduction as the ORIGIN study protocol did not include any weight change advice or any intervention towards weight modification. The randomized controlled LOOK-AHEAD trial investigated prospectively a comprehensive weight reduction program in patients with type 2 DM and a significant weight reduction was achieved. This intentional weight reduction, however, did not translate into improved total or CV survival of the patients. A post hoc analysis of the LOOK AHEAD Study has shown that if intentional weight reduction of more than 10% within 1 year can be achieved than a 20% lower CV disease risk can be observed (for composite of non-fatal acute MI or stroke, hospitalized angina, or CV death HR 0.8, 95% CI 0.65–0.99). A smaller weight reduction was, however, not effective. A lack of survival benefit from intentional weight loss was also reported in a long-term cohort study of 19 years follow-up in overweight patients with DM.

The current study may not allow conclusions on more advanced obesity. A recent report from a retrospective observations study showed that in more advanced obesity (mean BMI 45.1 kg/m²) weight reduction by gastrointestinal surgery resulted in improved mortality and CV event rates. This retrospective reports warrants confirmation in randomized clinical trials.

In the ORIGIN study, no intervention on body weight and no weight change advice were given within the study protocol. Therefore, the observed weight change in the study is either unintended or may result from individual weight loss attempts of patients at their own initiative. Other observational studies on weight change in DM without intentional weight management strategies could not show a benefit of weight reduction for improved prognosis. An analysis from the Veterans Health Administration (VHA) including 145 198 patients treated with oral antidiabetic therapy showed that weight loss of >5% body weight but not weight gain was consistently associated with higher risk of 5-year mortality. We have previously reported on weight change in patients with DM and CV comorbidity of the PROactive study. In this patient cohort, weight loss was associated with higher mortality compared to patients with no weight loss while weight gain had no negative effect. A nationwide longitudinal study in more than 11 million South Korean subjects showed that weight loss across all BMI categories was associated with increased mortality.

Taken together, interventional and observational studies in patients with DM and CV comorbidity did repeatedly not show a benefit for survival from intended weight reduction and suggest a higher risk associated with unintended weight loss. The widely held weight management recommendation is to promote weight reduction in any patient with BMI >25 kg/m² and irrespective of any CV comorbidity. Further research is needed to clarify if recommendations on weight management should differentiate more clearly between primary prevention and patients with established disease and advanced CV risk profiles.

The discussion is ongoing that other anthropometric measures such as waist circumference may yield better signals than BMI to assess CV risk. Combined models have shown that within BMI groups waist circumference can further subdivide patients for CV risk. However, BMI is the most widely used measure with well-defined categories and is strongly implemented in body weight management in both the medical and public domain. Therefore, the data on BMI in this representative patient population may be helpful to inform on individualized weight management.

Conclusions

Our investigation showed that in patients with type 2 DM and prevalent CV risk profile overweight and mild obesity are associated with lower all-cause mortality and CV mortality compared to patients with normal body weight (BMI 22–<25 kg/m²). In turn, patients with low body weight have a higher mortality. Weight loss was related to higher all-cause and CV mortality compared to no weight loss while weight gain was not. These findings are in contrast to conventional considerations on body weight in primary prevention.
