Infrared Safety in Factorized Hard Scattering Cross-Sections

Andrew Hornig, Christopher Lee, Grigory Ovanesyan
Ernest Orlando Lawrence Berkeley National Laboratory and University of California, Berkeley, CA 94720, USA

Abstract

The rules of soft-collinear effective theory can be used naively to write hard scattering cross-sections as convolutions of separate hard, jet, and soft functions. One condition required to guarantee the validity of such a factorization is the infrared safety of these functions in perturbation theory. Using $e^+e^-$ angularity distributions as an example, we propose and illustrate an intuitive method to test this infrared safety at one loop. We look for regions of integration in the sum of Feynman diagrams contributing to the jet and soft functions where the integrals become infrared divergent. Our analysis is independent of an explicit infrared regulator, clarifies how to distinguish infrared and ultraviolet singularities in pure dimensional regularization, and demonstrates the necessity of taking zero-bins into account to obtain infrared-safe jet functions.

1. Introduction

Factorization restores predictive power to calculations in Quantum Chromodynamics (QCD) which cannot be carried out exactly due to the contributions of nonperturbative effects. By separating perturbatively-calculable and nonperturbative contributions to observables in QCD and relating the nonperturbative contributions to different observables to each other, we gain the ability to make real predictions.

Proving factorization rigorously is a technically challenging undertaking, which traditionally has been formulated in full QCD [1,2]. More recently, many formal elements of these factorization proofs, such as power counting, gauge invariance, the organization of soft gluons into eikonal Wilson lines, and their torization proofs, such as power counting, gauge invariance, the organization of soft gluons into eikonal Wilson lines, and their torization proofs, have been organized in the framework of soft-collinear effective theory (SCET) [3-6]. These generic properties of the effective theory allow one to write at least nominally a formula “factorized” into collinear (jet) and soft functions for an arbitrary hard scattering cross-section in which strongly-interacting light-like particles participate [7]. Examples are the factorization of a large class of two-jet event shape distributions in $e^+e^-$ annihilation to light quark jets [8-10], jet mass distributions for $e^+e^-$ to top quark jets [11], or arbitrary jet cross-sections in $pp$ collisions independently of the choice of actual jet algorithm or observable [12]. While the formalism of SCET leads directly to expressing these observables as convolutions of separate hard, jet, and soft functions, blind use of this procedure without considering further specific properties of each chosen observable can hide whether factorization truly holds in a particular case or not.

An ideal set of observables for which to examine factorizability is the set of angularities $\tau_a$ [13], which are two-jet $e^+e^-$ event shapes dependent on a tunable parameter $a$ controlling how sensitive the event shape is to radiation along the jet axes or at wider angles. Varying $a$ between 0 and 1 interpolates between the thrust [14,15] and jet broadening [16] event shapes, but $a$ can take any value $-\infty < a < 2$ and give an infrared-safe observable in QCD. Angularities are known to be factorizable, however, only for $a < 1$ [13]. For events $e^+e^- \to X$, the angularity of a final state $X$ is

$$\tau_a(X) = \frac{1}{2} \sum_{i \in X} E_i \sin a \theta_i (1 - \cos \theta_i) \, 1^{1-a} = \frac{1}{2} \sum_{i \in X} |\vec{p}_i|^2 e^{-\eta_i/(1-a)},$$

where in the first form $E_i$ is the energy of particle $i$ and $\theta_i$ is the angle between its momentum and the thrust axis of $X$. In the second form, $\vec{p}_i$ is the momentum of particle $i$ transverse to the thrust axis, and $\eta_i$ is its rapidity with respect to the direction of the thrust axis. We assume all final-state particles are massless.

In a separate publication, using SCET, we calculate the angularity jet and soft functions to next-to-leading order in the strong coupling $\alpha_s$, resum large logarithms using renormalization group evolution, and model the nonperturbative soft function in a way that avoids renormalon ambiguities [17].

In this Letter, using angularity distributions as an example, we describe a simple, intuitive method for testing the validity of a factorization theorem deduced from the simple rules of SCET. We begin by naively presuming the factorizability of a given observable and then attempt to calculate perturbatively the one-loop jet and soft functions. If the factorization holds, each of these functions should be infrared-safe. If they are not, we learn immediately that the factorization breaks down.

Perturbative infrared-safety of jet and soft functions is not,
of course, by itself sufficient to guarantee validity of the proposed factorization theorem. The size of power corrections must also be taken into account. The methods we describe in this Letter address only the former issue, not the latter. (Power corrections for angularity distributions and their implications for factorizability were studied in [10], [13], [19].) However, our method is a quick and direct way to narrow down the class of observables for which a “generic” factorization deduced from SCET (e.g. [12]) could actually be valid.

Our analysis also sheds light on some issues related to infrared divergences in effective theory loop integrals. Finding a tractable regulator in SCET that suitably controls all infrared divergences has been very challenging (see, e.g., [19], [20]). Care is also required to define the effective theory such that it avoids double-counting momentum regions and infrared divergences of full theory diagrams. The procedure of zero-bin subtraction has been proposed to eliminate such double-counting [21].

We will address each of these issues without explicit calculation of the jet and soft loop integrals or use of an explicit infrared regulator. Instead we just examine the regions of integration surviving in the sum over all relevant diagrams. We will work in pure dimensional regularization, and learn how to identify \( 1/\varepsilon \) poles as infrared or ultraviolet in origin, clarifying the contribution made by scaleless integrals which are formally zero. We will thus conclude that the analysis is independent of the choice of any explicit IR regulator. In the process, we demonstrate the crucial role of zero-bin subtractions in obtaining physically-consistent, infrared-safe jet functions in angularity distributions for all \( a < 1 \). The ideas and methods illustrated through our discussion of angularity distributions are more generally applicable to other observables as well.

2. Angularity Distributions in SCET

The factorization theorem for the angularity distributions \( d\sigma/d\tau_a \) takes the form,

\[
\frac{1}{\sigma_0} \frac{d\sigma}{d\tau_a} = H(Q, \mu) \int d\tau_a^0 d\tau_a^1 \delta(\tau_a - \tau_a^0 - \tau_a^1 - \tau_a^2) \times J_a^0(\tau_a^0; \mu)J_a^1(\tau_a^1; \mu)S_a(\tau_a^2; \mu),
\]

where \( \sigma_0 \) is the total \( e^+e^- \rightarrow q\bar{q} \) Born cross-section, \( H \) is a hard function given in the effective theory by the square of a matching coefficient dependent only on short-distance effects, \( J_a^{0,1} \) are jet functions dependent on the partonic branching and evolution of each of the two back-to-back final state jets, and \( S_a \) is a soft function dependent on the low energy radiation from the jets and the color exchange between them. All the functions depend on the factorization scale \( \mu \), with this dependence cancelling in the full cross-section. The factorization theorem Eq. (2) for angularity distributions has been proved in full QCD [13] and in SCET [10], [18], for \( a < 1 \), where this condition was derived from the size of power corrections induced by replacing the thrust axis implicit in Eq. (1) with the collinear jet axis in SCET [10], [13]. Our attempt to calculate perturbatively the jet and soft functions in Eq. (2) will provide a complementary way to deduce this condition and an intuitive explanation of the absence of infrared divergences in the jet and soft functions for \( a < 1 \) and their appearance for \( a \geq 1 \).

Collinear and soft modes in SCET are distinguished by the scaling of the momenta of the particles they describe. The light-cone momenta \( p = (n \cdot p, \bar{n} \cdot p, p_\perp) \) of collinear modes, where \( n, \bar{n} \) are light-cone vectors in the \( z\bar{z} \) directions, scale as \( Q(l^2, 1, \lambda) \) and \( Q(1, l^2, \lambda) \), and soft modes as \( Q(l^2, 2, \lambda^2) \). \( Q \) is the hard energy scale in the process being considered (here, the center-of-mass energy in \( e^+e^- \) collisions), and \( \lambda \) is a small ratio of energy scales, here \( \lambda = \sqrt{Q_{\text{coll}}/Q} \). Collinear momenta \( p \) are split into a “label” piece \( \hat{p}_i \) containing the order \( Q \) and \( Ql \) momenta, and a “residual” piece \( k_c \) of all whose components are order \( Ql^2 \). A redefinition of the collinear fields through multiplication by soft Wilson lines decouples soft and collinear modes in the SCET Lagrangian to leading order in \( \lambda \) [6].

The soft function \( S_a \) in Eq. (2) is defined by

\[
S_a(\tau_a^2; \mu) = \frac{1}{N_C} \text{Tr} \left( \sum_{\alpha \beta} \delta(\tau_a^\alpha - \tau_a^0\bar{n}) \hat{Y}_a(\mu) \hat{Y}_a(0) \bar{Y}_a(0) \right) \left( \sum_{\alpha \beta} \delta(\tau_a^\alpha - \tau_a^1 \bar{p}) \hat{Y}_a(\mu) \hat{Y}_a(0) \bar{Y}_a(0) \right),
\]

and the jet functions \( J_a^{0,1} \) by

\[
J_a(\tau_a^0; \mu) \frac{\delta}{\delta \tau_a^0} = \frac{1}{N_C} \text{Tr} \left( \frac{d}{d\tau_a^0} \int \frac{dq^+}{2\pi} \int d^2x e^{i\mathbf{k} \cdot \mathbf{x}} \times \sum_{\alpha \beta} \delta(\tau_a^\alpha - \tau_a^0\bar{n}) \hat{X}_a(\mu) \hat{X}_a(0) \right),
\]

and similarly for \( \bar{Y}_a \), with the bar denoting the anti-fundamental representation. The fields \( \hat{X}_a \) in the jet function are the product of collinear Wilson lines and quarks, \( \hat{X}_a = W_a \hat{C}_a \), where

\[
Y_a(z) = \exp \left[ i g \int_0^\infty ds \, n \cdot A_s(nz + z) \right],
\]

and similarly for \( \bar{Y}_a \). The soft Wilson line \( W_a \) in the soft function is the path-ordered exponential of soft gluons,

\[
W_a(z) = \exp \left[ i g \int_0^\infty ds \, \bar{n} \cdot A_s(nz + z) \right],
\]

and similarly for \( \bar{W}_a \). The operator \( \hat{\tau}_a \) acts on final states \( |X\rangle \) according to

\[
\hat{\tau}_a |X\rangle = \frac{1}{Q} \sum_{n=1}^{\infty} \left| p_\perp \right| e^{-\mathbf{p}_\perp(1-a)z} |X\rangle,
\]

and is constructed from the energy-momentum tensor \( T_{\mu\nu} \) [22], and the operators \( T_{\mu\nu}^{n,\bar{n},s} \) in Eqs. (5) and (6) are constructed by keeping only the \( n, \bar{n} \)-collinear or soft terms in \( T_{\mu\nu} \) [10]. For further details of the SCET Lagrangian and the Feynman rules, we refer the reader to Refs. [4], [5], [6].

Next we proceed to examine the infrared behavior of \( \langle \alpha_s \rangle \) contributions to the soft and jet functions of Eqs. (5) and (6) calculated in perturbation theory.
3. Divergences in the Soft Function

The soft function is calculated from the cut diagrams in Fig. 1 with an additional delta function \( \delta(\tau^a - \tau_a(X)) \) inserted along the cut, where \( X \) is the final state created by the cut, and \( \tau_a(X) \) is given by Eq. (1). This modified cutting rule is required by the insertion of the \( \delta(\tau^a - \tau_a) \) operator in Eq. (3) [17].

In diagrams (A) and (B) of Fig. 1 with a virtual gluon, this delta function takes the general form

\[
S_a(\tau_a) = A \delta(\tau_a) + \sum_{\alpha} B_n \left[ \frac{\theta(\tau_a)}{\tau_a} \right]_+. \tag{8}
\]

Since the virtual diagrams are proportional to \( \delta(\tau^a) \), to study how they cancel the IR poles in the real diagrams, we only need to isolate the coefficient \( A \) of \( \delta(\tau^a) \). By integrating all the diagrams over \( \tau_a \) between 0 and 1, using the property of the plus functions \( \int_0^1 dx [\theta(x)(\log^n x)/x]_+ = 0 \), we isolate \( A \). We will denote as \( I^V_a \) and \( I^R_a \) respectively the virtual and real diagrams’ contributions to \( A \).

The virtual diagrams’ contribution to \( A \) is

\[
I^V_a = \frac{\alpha_s C_F}{\pi} \frac{4\pi^2 \mu^2}{\Gamma(1 - \epsilon)} \int_0^1 dk^+ \int_0^\infty dk^- (k^+ k^-)^{-1-\epsilon}, \tag{9}
\]

whose integration region is the entire first quadrant of the \( k^+ k^- \) plane as shown in Fig. 2A.

In the real gluon diagrams, the cut creates a state \( X \) with a single soft gluon, and the operator \( \delta(\tau^a - \tau_a(X)) \) acting on \( X \) introduces the delta function \( \delta(\tau^a - \tau_a(X)) \) into the integral over the gluon momentum \( k \), where

\[
\tau_a(X) = \begin{cases} 
\frac{1}{Q} |k^+|^{-1} |k^-|^2 & \text{for } k^- \geq k^+ \\
\frac{1}{Q} |k^+|^{-1} |k^-|^2 & \text{for } k^- < k^+.
\end{cases} \tag{10}
\]

Figure 1: The (A), (B) virtual and (C), (D) real gluon contributions to the soft function. The gluons all have momentum \( k \).

The virtual diagrams thus contribute

\[
I^V_a = \frac{\alpha_s C_F}{\pi} \frac{4\pi^2 \mu^2}{\Gamma(1 - \epsilon)} \int_0^\infty dk^+ \int_0^\infty dk^- (k^+ k^-)^{-1-\epsilon} \tag{11}
\]

to \( A \). \( I^V_a \) depends explicitly on \( a \) through the integration region determined by the delta function \( \delta(\tau^a - \tau_a(X)) \), restricting gluon momenta \( k \) to the region \( S_a \), given by \( k^+ > 0 \) and

\[
(k^-)^2(k^+)^{-1} < Q \quad \text{for } k^- \geq k^+ \quad (k^-)^2(k^+)^{-1} < Q \quad \text{for } k^- < k^+. \tag{12}
\]

This region is plotted in Fig. 2A for \( a = 0 \).

The virtual and real integrals \( I^V_a + I^R_a \) contain exactly the same integrand, but with opposite relative signs and integrated over different regions of the \( k^+ k^- \) plane. Thus, in the sum of the virtual and real integrals \( I^V_a + I^R_a \), the integrals over the overlapping part of the regions cancel, leaving an integral over the region \( S_a \), as illustrated in Fig. 2B.

In Fig. 3, we plot the integration regions resulting from the sum of virtual and real diagrams for several other values of \( a \). For \( a \leq 0 \), the resulting region of integration \( S_a \) always satisfies \( k^+ \geq Q \), and is manifestly a purely UV region. Between 0 < \( a < 1 \), \( k^+ \) approach zero on the boundaries, but the product \( k^+ k^- \) remains always greater than \( Q^2 \), so divergences in the soft loop integral are still purely UV. For \( a = 1 \), the boundary of the region is the line of constant \( k^+ k^- = Q^2 \). For \( a > 1 \), the boundary drops below this line, so, as \( k^+ \to \infty \), the product drops to \( k^+ k^- \to 0 \) in the region along the boundary. But such momenta are in fact collinear. The sum of soft diagrams
still contains contributions from collinear modes. Continuing to explicitly evaluate $I_R^a + I_V^a$, we find this sum of integrals is convergent for $a < 1$ when $\epsilon > 0$, so the poles are $1/\epsilon_{\text{UV}}$, but not for $a \geq 1$, in which case uncancelled IR divergences remain.

The shapes of the regions in Figs. 2 and 3 also tell us how using an explicit IR regulator would affect our analysis, and in fact teaches us that the choice of regulator must be made with care. For example, we might choose an effective cutoff $\lambda$ on $k^2$ in soft loop integrals as above avoids confusion about the consistency of the regulator itself.

We draw two lessons from the analysis thus far. The first is that in pure dimensional regularization, the coefficient of $(1/\epsilon_{\text{UV}} - 1/\epsilon_{\text{IR}})$ in a virtual diagram cannot be determined from the virtual diagram alone, but only together with the real diagram whose IR divergence it is supposed to cancel (cf. [25]). The reason that the virtual subtraction can depend on $\epsilon$ even though by itself it is independent of $\epsilon$ is that the area of overlap between the integration regions of real and virtual diagrams depends on $\epsilon$. The second is that the presence or absence of IR divergences in the sum of all contributing loop integrals can (and should) be determined before completely evaluating the integral with a given IR regulator. Looking at the shape of the region of integration in momentum space as above avoids confusion about the consistency of the regulator itself.

4. Divergences in the Jet Function

Now we analyze the jet functions Eq. (4) at $O(\alpha_s)$ in perturbation theory. We will observe the same breakdown of infrared safety as $a \to 1$ due to the momentum regions beginning to include IR divergent regions. We will consider just the jet function $F_n^a(\tau_n^a)$; identical analysis applies to $F_n^L(\tau_n^L)$.

The diagrams contributing to $F_n^L(\tau_n^L)$ in Eq. (4a) are shown in Fig. 4. In graphs (A) and (B), the gluon is emitted from a collinear Wilson line $W_a$ or $W_b^\perp$ in the jet fields $x_{n+1}$. The sum of graphs (C) and (D) is equivalent to graphs in full QCD by a field redefinition [26,27] and is manifestly IR finite for all $a < 2$, and we will not consider them further here [17]. The total momentum flowing through each diagram is $Qn/2 + l$, with the label component $Qn/2$ specified by the labels on the jet fields in the matrix elements in Eq. (4a), and $l$ the residual momentum. The total momentum of the gluon in each loop is $q = \tilde{q} + q_r$, where $\tilde{q}$ is the label momentum and $q_r$ the residual momentum. The diagrams must be cut in all possible places, and a delta function $\delta(\tau_n^a - \tau_a(x_{n+1}))$ inserted along each cut. To obtain $F_n^L(\tau_n^L)$ we then integrate over $l'$ according to Eq. (4).

An integral over the collinear gluon momentum $q$ is a sum over $\tilde{q}$ and an integral over $q_r$. The sum includes the value $\tilde{q} = 0$. The sum and integral can be combined into a single continuous integral over the total $q$ if a “zero-bin subtraction” is also taken [21], which avoids the double-counting of soft contributions between the soft and jet functions [13,18,20,25,28]. Below we will refer to integrals or graphs before the zero-bin subtraction as “naive”, and after the subtraction “collinear”.

Virtual graphs and zero-bin subtractions in pure dimensional regularization again contain scaleless integrals, which are zero, but as we observed in the calculation of the soft function, we must examine the regions of integration to observe how the cancellation of IR divergences among all the graphs occurs.

Diagrams created by cuts through the single quark propagator in graphs (A) and (B) in Fig. 4 leave a virtual gluon loop and are proportional to $\delta(\tau_n^a)$, whose coefficient we extract. The naive virtual graph contributes

$$\tilde{I}_n^V = -\frac{\alpha_s C_F}{\pi} \frac{(4\pi\mu^2)^\epsilon}{(1-\epsilon)} \int_0^Q dq^- \int_0^\infty dq^\perp \frac{1}{(q^2)^{1+\epsilon}} \left( \frac{1}{\epsilon} - \frac{1}{Q} \right),$$

which goes over region $\tilde{V}$ in Fig. 5. The zero-bin subtraction from the virtual graph is

$$I_{n0}^V = -\frac{\alpha_s C_F}{\pi} \frac{(4\pi\mu^2)^\epsilon}{(1-\epsilon)} \int_0^\infty dq^- \int_0^Q dq^\perp \frac{1}{(q^2)^{1+\epsilon}} \frac{1}{q^-},$$

which goes over the whole first quadrant, region $\tilde{V}_0$ in Fig. 5. So the total virtual collinear contribution $I_n^V = \tilde{I}_n^V - I_{n0}^V$ is

$$I_n^V = -\frac{\alpha_s C_F}{\pi} \frac{(4\pi\mu^2)^\epsilon}{(1-\epsilon)} \int_0^Q dq^- \int_0^\infty dq^\perp \frac{1}{(q^2)^{1+\epsilon}} \left[ \int_Q^\infty dq^- + \int_0^Q dq^- \right],$$

where the $1/q^-$ term is integrated over region $\tilde{V}$ in Fig. 5 and the $1/Q$ term over $\tilde{V}$.

Now we add the contribution of the graphs (A) and (B) in Fig. 4 cutting through the gluon loop, creating a final state $X_{qg}$ with a collinear quark and gluon, with

$$\tau_a(X_{qg}) = \frac{1}{Q} \left[ (q^-)^2 (q^\perp)^{-1+\epsilon} + (Q-q^-)^2 (l^-q^\perp)^{-1+\epsilon} \right],$$

and insert $\delta(\tau_n^a - \tau_a(x_{n+1}))$ into the integral over the gluon momentum $q$. As in the case of the soft function, we need only to isolate the coefficient of $\delta(\tau_n^a)$ in the jet function $F_n^a(\tau_n^a)$ to study the cancellation of IR divergences with the virtual graphs. We do so by again integrating over $0 < \tau_a < 1$.

The contribution to the coefficient of $\delta(\tau_n^a)$ from the naive Wilson line graphs (A) and (B) in Fig. 4 with a cut through the gluon loop is

$$I_n^R = -\frac{\alpha_s C_F}{\pi} \frac{(4\pi\mu^2)^\epsilon}{(1-\epsilon)} \int_R dq^- dq^\perp \frac{1}{(q^2)^{1+\epsilon}} \left( \frac{1}{\epsilon} - \frac{1}{Q} \right),$$
where $\tilde{R}$ is the region in the first quadrant of the $q^-, q_1^-$ plane under the curve

$$q_1^- = \left\{ Q \left[ \frac{1}{(Q - q^-)^{1-a}} + \frac{1}{(q^-)^{1-a}} \right]^{\frac{1}{1-a}} \right\}^{\frac{1}{1-a}}, \tag{18}$$

shown for $a = 0$ in Fig. 6. The zero-bin subtraction is

$$I_n^R = \frac{\alpha_s C_F}{\pi} \left[ 4\pi \mu_F^2 \right]^f \frac{1}{\Gamma(1 - \epsilon)} \int_{R_0} dq^- dq_1^- \frac{1}{(q_1^-)^{1+\epsilon}} \frac{1}{q^-}, \tag{19}$$

where $R_0$ is the region given by $q^- > 0$ and

$$0 < q_1^- < \left[ Q(q^-)^{1-a} \right]^{\frac{1}{1-a}}, \tag{20}$$

shown for $a = 0$ in Fig. 6. Subtracting the two integrals, $I_n^R = I_n^R - I_n^{a \text{th}}$, yields the correct collinear integral,

$$I_n^R = -\frac{\alpha_s C_F}{\pi} \left[ 4\pi \mu_F^2 \right]^f \frac{1}{\Gamma(1 - \epsilon)} \left[ \int_{\tilde{R}} dq^- dq_1^- \frac{1}{(q_1^-)^{1+\epsilon}} \frac{1}{q^-} \right. \right.$$

$$\left. + \int_{R_0} dq^- dq_1^- \frac{1}{(q_1^-)^{1+\epsilon}} \frac{1}{Q} \right], \tag{21}$$

where the first integral goes over the region $R$ formed by removing $\tilde{R}$ from $R_0$, illustrated in Fig. 6 for $a = 0$. The second integral, containing $1/Q$, still goes over $\tilde{R}$.

Thus, the sum $I_n = I_n^R + I_n^{a \text{th}}$ of the collinear virtual and real graphs is

$$I_n = -\frac{\alpha_s C_F}{\pi} \left[ 4\pi \mu_F^2 \right]^f \frac{1}{\Gamma(1 - \epsilon)} \left[ \int_{J_1 - J_2} dq^- dq_1^- \frac{1}{(q_1^-)^{1+\epsilon}} \frac{1}{q^-} \right.$$

$$\left. - \int_{\tilde{R} - R_0} dq^- dq_1^- \frac{1}{(q_1^-)^{1+\epsilon}} \frac{1}{Q} \right], \tag{22}$$

where the regions $J_{1,2}$ are shown in Fig. 7 for several values of $a$, and the notation $J_1 - J_2$ means the integrand has an extra minus sign in $J_2$. $J_2$ contains only UV divergences. For all $a < 1$, $J_1$ avoids the boundary at $q^- = 0$, and the integral is convergent for $\epsilon > 0$. The $1/\epsilon$ poles in this integral, as well as in the integral on the second line of Eq. (22), are then purely UV. For $a = 1$, however, the region $J_1$ reaches the boundary at $q^- = 0$, and the integral is no longer finite. The jet function is not infrared safe for $a \geq 1$, just as we found for the soft function.

Although the full distribution $d\sigma/d\tau_a$ is infrared safe for $a < 2$, for $a \geq 1$, contributions of the soft and collinear modes of SCET with the momentum scalings specified in Sec. 2 (so-called SCET$_I$ modes) do not entirely separate from each other. The soft integration regions illustrated in Fig. 3 for $a \leq 1$ grow for $a > 1$ to include the contribution of collinear modes, and the collinear integration regions in Fig. 2 grow to include modes which are soft. Angularity distributions with $a \geq 1$ are dominated by jets so narrow that collinear and soft modes have the same virtuality of order $\Lambda_{\text{QCD}}$. We observe this in a full calculation of the jet and soft functions to $O(\alpha_s)$ [17], which manifests the natural scales in the jet and soft functions where large logarithms are minimized, $\mu_f = Q r_a^{1/(2-a)}$ and $\mu_S = Q r_a$, which become equal at $a = 1$. Thus, the separation of scales required by the formalism of SCET$_I$ no longer holds. In this case, the modes may be distinguished by their rapidity, as was proposed in the formalism of SCET$_{\tilde{I}}$ [21].

5. Conclusions

Although hard-scattering cross-sections can be written formally in a factorized form based on naïve application of a formalism such as SCET, the properties of the chosen observable determine whether or not the effective theory is applicable and, so, whether the factorization theorem is actually valid. Such a theorem must pass a number of tests. The method we have presented is a straightforward and intuitive test of the infrared-safety of jet and soft functions in a proposed factorization theo-
rem. We illustrated the method at $O(\alpha_s)$ for angularities, whose tunable parameter $a$ allowed us to study the continuous progression from infrared-safety of jet and soft functions for $a < 1$ to its breakdown for $a \geq 1$, but the method is more generally applicable to other observables as well. The test will reveal those observables for which the naive SCET$_I$ factorization fails. Through our analysis, we have illustrated the crucial role of zero-bin subtractions in effective field theory, and the manner in which scaleless integrals in pure dimensional regularization convert IR into UV divergences in infrared-safe quantities, without choosing any ad hoc prescriptions, allowing one to classify IR and UV divergences independently of an explicit IR regulator.

Acknowledgements

We are grateful to C. Bauer for many valuable discussions, constant encouragement, and extensive feedback on the draft. We also thank I. Stewart for useful discussions, and B. Lange and Z. Ligeti for careful review of the draft. CL and GO are grateful to the Institute for Nuclear Theory at the University of Washington for its hospitality during a portion of this work.
