We compute the circuit complexity of scalar curvature perturbations on Friedmann-Lemaître-Robertson-Walker cosmological backgrounds with a fixed equation of state \( w \) using the language of squeezed vacuum states. Backgrounds that are accelerating and expanding, or decelerating and contracting, exhibit features consistent with chaotic behavior, including linearly growing complexity. Remarkably, we uncover a bound on the growth of complexity for both expanding and contracting backgrounds \( \lambda \leq \sqrt{2} |H| \), similar to other bounds proposed independently in the literature. The bound is saturated for expanding backgrounds with an equation of state more negative than \( w = -5/3 \), and for contracting backgrounds with an equation of state larger than \( w = 1 \). For expanding backgrounds that preserve the null energy condition, de Sitter space has the largest rate of growth of complexity, and we find a scrambling time that is similar to other estimates up to order 1 factors.

I. INTRODUCTION

The relatively new concept called circuit complexity—conceptually defined as the minimum number of quantum gates necessary to construct a desired target state from a given reference state—has found several interesting applications in recent years. For example, it may play an important role in probing physics behind the horizon of an eternal anti-de Sitter (AdS) black hole through the “complexity = volume” and “complexity = action” proposals [1–4]. Recent studies have also explored different methods of calculating circuit complexity based on the position space wave function or covariance matrix [5–11], using the geometric technique pioneered by Nielsen [12], and they have extended the idea of complexity to quantum field theory [5,13–20]. More generally, complexity can serve as one of several diagnostics for determining if a quantum system displays quantum chaos [21–23].

We are interested here in the application of circuit complexity to cosmology in order to gain new insights about cosmological evolution and structure formation from a quantum information theoretic perspective. In particular, cosmological perturbations in Friedmann-Lemaître-Robertson-Walker (FLRW) backgrounds can be described in the language of two-mode squeezed states [24–27]. The squeezed state formalism allows the straightforward use of the geometric techniques described above for computing the cosmological complexity of cosmological perturbations, first described in [28]. The preliminary study [28] only studied two simple expanding cosmological backgrounds: de Sitter (or cosmological constant-dominated), and radiation-dominated. For expanding de Sitter backgrounds, the cosmological complexity is small at early times while the mode is within the horizon, but it grows linearly with the logarithm of the scale factor after the mode exits the horizon. Because the linear growth of complexity is a characteristic [22] of quantum chaos, Ref. [28] proposed that cosmological perturbations in de Sitter space are (quantum) chaotic. The behavior of complexity for expanding radiation solutions found in [28], however, is quite the opposite. While the mode is outside the horizon, the complexity is decreasing linearly with the logarithm of the scale factor, and it “freezes-in” once the mode reenters the horizon at late times.
This suggests that cosmological perturbations in an expanding radiation background are not chaotic, in contrast with the de Sitter case. We stress that in our analysis we are computing the complexity for the curvature perturbations in the $3 + 1$ cosmological background themselves, and our analysis does not have a direct relationship to the specific applications of complexity to AdS/CFT or holography (in particular, there is no dual holographic theory in use here).

In this work, we aim to extend this analysis of the cosmological complexity of cosmological perturbations to a broader set of backgrounds. In particular, we will analyze the behavior of the squeezing parameters and complexity for backgrounds with an arbitrary constant equation of state $w$, encompassing both accelerating and decelerating backgrounds. We find that the squeezing and complexity for accelerating and decelerating (expanding) backgrounds behave qualitatively similar to their de Sitter and radiation counterparts from [28]: accelerating solutions show signs of quantum chaos, with complexity growing as modes exit the horizon, while the complexity for decelerating solutions decays until the mode reenters the horizon. Interestingly, we find that the slope of the growing complexity for accelerating backgrounds increases with decreasing equation of state $w$ until reaching a “threshold” value $w = -5/3$, after which the slope is fixed. This implies a bound on the rate of change of complexity, which we calculate to be $dC/dt \leq \sqrt{2} H$. We conjecture that this bound is related to a similar bound on the Lyapunov exponent for out-of-time-ordered correlators [29]. For backgrounds that satisfy the null energy condition, de Sitter has the largest complexity growth, suggesting it is maximally chaotic among these backgrounds. We also conjecture a scrambling time for cosmological perturbations, finding rough agreement with other results in the literature [30–32].

Further, we will extend our analysis to include contracting as well as expanding backgrounds, finding that the squeezing and complexity for decelerating contracting backgrounds behave qualitatively similar to accelerating contracting backgrounds. Contracting backgrounds will obey an identical bound on the growth rate of complexity, saturating the bound for equations of state larger than $w = 1$.

In Sec. II we review some important details about the description of cosmological perturbations as two-mode squeezed states, and we find approximate analytic solutions for the squeezing parameters for expanding and contracting backgrounds. We confirm these analytic solutions by qualitatively comparing them to numerical solutions to the squeezing equations of motion for a variety of equations of state. In Sec. III we use the squeezing solutions found in Sec. II to find approximate analytic solutions for the cosmological complexity, uncovering the bound on complexity growth and the scrambling time. We conclude with some discussion, speculation, and potential future work in Sec. IV.

II. SQUEEZED COSMOLOGICAL PERTURBATIONS

We begin our analysis by reviewing the description of cosmological perturbations [33] as two-mode squeezed states, following [28] (see also [24–27]). We take as our background a spatially flat Friedmann-Lemaître-Robertson-Walker (FLRW) metric

$$ds^2 = -dt^2 + a(t)^2 d\vec{x}^2 = a(\eta)^2 (-d\eta^2 + d\vec{x}^2),$$

where we have introduced the conformal time $\eta$. For simplicity, we will consider our matter content to consist of a fundamental scalar field $\phi$ with a canonical kinetic term and potential $V(\phi)$. On the background (1) the scalar field is homogeneous and time-dependent $\phi_0(t)$; the scalar field potential and kinetic energy source the evolution of the scalar field $a(\eta)$.

On this background, we will consider fluctuations of a scalar field $\phi(x,t) = \phi_0(t) + \delta\phi(t,x)$ with the metric

$$ds^2 = a(\eta)^2 \{-[1 + 2(\phi(\eta,\eta))d\eta^2 + [1 - 2(\phi(x,\eta))]d\vec{x}^2\}.$$  

In terms of the curvature perturbation $\mathcal{R} = \psi + H/2\delta\phi$, where a dot denotes a derivative with respect to cosmic time $t$, and the Hubble parameter $H = \dot{a}/a$, the action takes the following simple form [33]:

$$S = \frac{1}{2} \int dt d^3x a^2 \phi^2 \left[\mathcal{R}^2 - \frac{1}{a^2} (\partial_\mu \mathcal{R})^2 \right].$$

By using the Mukhanov variable $v \equiv \zeta \mathcal{R}$, where $\zeta = -1/\sqrt{2\epsilon}$, with $\epsilon = -H^2/3 = 1 - \mathcal{H}^2/\mathcal{H}_*^2$, the action can be transformed into the following form:

$$S = \frac{1}{2} \int d\eta d^3x \left[v^2 - (\partial_\mu v)^2 + \left(\frac{\zeta'}{\zeta}\right)^2 v^2 - 2 \frac{\zeta'}{\zeta} v' v\right],$$

where the prime denotes a derivative with respect to conformal time, and $\mathcal{H} = a'/a$. The last term in (4) is usually removed by an integration by parts, but we will retain this form for our analysis. This action represents perturbations of a scalar field coupled to an external time-varying source.\(^2\) We promote the perturbation to a quantum field and expand into Fourier modes $\hat{v}_k$, with the action

$$S = \frac{1}{2} \int d\eta d^3k \left\{\hat{v}_k \hat{v}_{-k}^\dagger - \left[k^2 - \left(\frac{\zeta'}{\zeta}\right)^2 \right] \hat{v}_k \hat{v}_{-k} - 2 \frac{\zeta'}{\zeta} \hat{v}_k \hat{v}_{-k}'\right\}.$$  

Note that after an appropriate change of variables, this action corresponds to an inverted harmonic oscillator for each individual Fourier mode [26–28]. The quantum system defined by this action is the one we will consider for our calculations of complexity.

We define the usual creation and annihilation operators in terms of the Fourier modes of the perturbation $\hat{v}_k = \frac{1}{\sqrt{2k}} (\hat{c}_k + \hat{c}_k^\dagger)$, $\hat{v}_k' = -i \frac{k}{2} (\hat{c}_k - \hat{c}_k^\dagger)$.

\(^1\)It would be interesting to study the effect that more general matter content has on the behavior of squeezed states and complexity, as in [25], though we leave these investigations to future work.

\(^2\)A virtually identical-looking expression can also be derived for tensor perturbations with the replacement $\zeta'/\zeta \to a'/a$, and our results will hold for these types of perturbations as well.
The unitary evolution $U_k$ of a state can be parametrized in the factorized form \[ U_k = \hat{S}(r_k, \phi_k)\hat{R}_k(\theta_k), \] where $\hat{R}_k$ is the two-mode rotation operator \[ \hat{R}_k(\theta_k) = \exp[-i\theta_k(\eta)(\hat{c}_k\hat{c}_k^\dagger + \hat{c}_k^\dagger\hat{c}_k)], \] written in terms of the rotation angle parameter $\theta_k(\eta)$, and $\hat{S}_k$ is the two-mode squeeze operator \[ \hat{S}_k(r_k, \phi_k) = \exp\left[\frac{r_k(\eta)}{2}(\hat{c}_k^\dagger\hat{c}_k - e^{2i\phi_k(\eta)}\hat{c}_k\hat{c}_k^\dagger)\right], \] written in terms of the squeezing parameter $r_k(\eta)$ and squeezing angle $\phi_k(\eta)$. For our case, the rotation operator and rotation angle $\theta_\eta$ are not important, therefore they will be dropped in the subsequent analysis. As, since the squeezing equations of motion will only depend on the magnitude $k$ of the wave number $k$, we have suppressed the vector notation on the subscripts of these parameters.

The two-mode vacuum is annihilated by $\hat{c}_k$, \[ \hat{c}_k|0\rangle_k = 0, \quad \forall k. \] The two-mode squeeze operator acting on this vacuum then results in a two-mode squeezed vacuum state \[ |\Psi_{\text{sq}}\rangle_k = \hat{S}(r_k, \phi_k)|0\rangle_k = \frac{1}{\cosh r_k} \sum_{n=0}^{\infty} (-1)^n e^{-2n\phi_k} \tan^\beta r_k |n\rangle_k|\rangle_k. \]

Note that the parameter $\beta = -2/(1 + 3w)$ is positive for accelerating solutions and negative for decelerating solutions. We will treat the marginal $w = -1/3$ case separately at the end of this subsection. The equations of motion (13) and (14) can now be written entirely in terms of the scale factor by inverting (15), giving \[ \frac{dr_k}{da} = -\frac{1}{a} \cos(2\phi_k), \] \[ \frac{d\phi_k}{da} = \frac{k|\eta_0|}{|\beta|} \frac{1}{a^{1+1/\beta}} + \frac{1}{a} \coth(2r_k) \sin(2\phi_k). \] The behavior of the solutions (16) and (17) depends crucially on whether the background is accelerating or decelerating, so we will study these cases separately.

Beginning with accelerating backgrounds $w < -1/3$, we will see in our analysis below that the behavior of the solutions depends qualitatively on the numerical value of $\beta$, which specifies the equation of state of the background. An accelerating background equation of state that obeys the null energy condition $-1 \leq w < -1/3$ has the range $1 \leq \beta < \infty$, where $\beta = 1$ corresponds to a de Sitter background $w = -1$. Equations of state that violate the null energy condition $w < -1$ thus fall in the range $0 < \beta < 1$.

where the two-mode excited state is \[ |n\rangle_k|n\rangle_k = \sum_{n=0}^{\infty} n! (\hat{c}_k^{\dagger})^n (\hat{c}_k^{\dagger})^n |0\rangle_k|\rangle_k. \] The time evolution of the squeezing parameters $r_k(\eta)$, $\phi_k(\eta)$ is determined by the Schrödinger equation and leads to the differential equations for $r_k(\eta)$ and $\phi_k(\eta)$ with the scale factor $a$ as the independent variable, \[ \frac{dr_k}{da} = -\frac{1}{a} \cos(2\phi_k), \] \[ \frac{d\phi_k}{da} = \frac{k}{aH} + \frac{1}{a} \coth(2r_k) \sin(2\phi_k). \]

Note that $\mathcal{H}(a) \equiv a'/a$ is implicitly defined in terms of the scale factor $a$. In the following subsections, we will specify the background $a(\eta)$ for a fixed equation of state for expanding and contracting cosmologies, which will allow us to solve the equations of motion (13) and (14) as a function of the scale factor.

### A. Expanding backgrounds

We will begin by considering expanding FLRW backgrounds (1) with a fixed equation of state $p = w\rho$. The scale factor as a function of conformal time depends on whether the background is accelerating or decelerating through the convenient parameter $\beta \equiv -2/(1 + 3w)$.

At sufficiently early times $a \ll 1$, perturbation modes start inside the horizon for all accelerating solutions. Solutions to (16) and (17) start with small squeezing $r_k \ll 1$ and approximately constant squeezing angle \[ r_k(a) \approx \frac{\beta}{2k|\eta_0|} a^{1/\beta}, \] \[ \phi_k(a) \approx \frac{\pi}{4} - \frac{1}{4k|\eta_0|} a^{1/\beta}. \] up to subleading corrections of higher order in $a$. The mode exits the horizon when $k \sim \mathcal{H}$ or equivalently when $k|\eta_0| \sim \beta a^{1/\beta}$, which is when the first term in the squeezing angle equation of motion (17) balances the coefficient of the second term.

After the mode exits the horizon, the squeezing angle asymptotically approaches $-\pi/2$ as $a \gg 1$ and the squeezing parameter grows logarithmically with the scale factor and becomes large, $r_k \gg 1$. The form of the solutions turns out to depend on the value of $\beta$.

\[ r_k(a) \approx \ln a, \]
φ in Fig. 1, shown for different choices of the equation of state discussed in Sec. III.

Inhomogeneous
Homogeneous

φ(\eta) \approx -\frac{\pi}{\beta} + \frac{1}{2} \frac{k|\eta_0|}{2\beta - 1} + \frac{B}{a^2}, \quad (21)

where B is an arbitrary constant dependent on initial conditions, and we have included both the inhomogeneous (independent of k) and homogeneous (dependent on k) subleading solutions for the squeezing angle. For β > 1/2, corresponding to w > -5/3, the inhomogeneous solution for the squeezing angle dominates for a → 1. Alternatively, for β < 1/2, corresponding to w < -5/3, the homogeneous solution dominates the subleading behavior of the squeezing angle. For certain initial conditions, these two terms can switch roles temporarily—see Appendix. Oddly, this transition between the behaviors does not occur at the boundary of null energy violation w = -1, corresponding to β = 1. The transition at β = 1/2 can be traced to the factor of 2 in the sin(2φ_k) term of (21), corresponding to the two-mode structure of the squeezed state, though its deeper physical origin is less clear. For β = 1/2, we need to modify the solution (21) to include an additional factor of ln a since the powers of the homogeneous and inhomogeneous solutions are the same. Putting all of these conditions together, we have the solutions

r_k(a) = \begin{cases} 
\ln(a) + O(\frac{1}{\eta_0}), & \beta \geq 1/2, \\
\ln(a) + O(1), & \beta < 1/2,
\end{cases} \quad (22)

for the squeezing parameter and

φ_k(a) = \begin{cases} 
\frac{\pi}{2} + \frac{k|\eta_0|}{2\beta - 1} + \frac{1}{a^\beta}, & \beta > 1/2 (w > -5/3), \\
\frac{\pi}{2} + \frac{\beta}{a^\beta} + \frac{\ln a}{\beta}, & \beta = 1/2 (w = -5/3), \\
\frac{\pi}{2} + \frac{\beta}{a^\beta}, & \beta < 1/2 (w < -5/3)
\end{cases} \quad (23)

for the squeezing angle.

We can see the general behavior of the early-time solutions (18) and (19) and late-time solutions (22) and (23) in the numerical solutions to the equations of motion (16) and (17) in Fig. 1, shown for different choices of the equation of state w (equivalently different values of β). In particular, we note that at early times the squeezing parameter r_k(a) is small, then grows as ~ ln a after the mode exits the horizon, with the same slope for all equations of state, while the squeezing angle φ_k after the mode exits the horizon asymptotically approaches -π/2 in a way that depends on the equation of state. This behavior is qualitatively similar to that of de Sitter solutions (w = -1) found in [25,28].

Before we consider the decelerating solutions, we point out that for an equation of state above the “threshold” value w = -5/3 identified in (22) and (23), the subleading behavior of the squeezing angle φ_k(a) depends on the equation of state through the power of the scale factor a^{1/\beta}. As the equation of state decreases past w = -5/3, the subleading behavior of the squeezing angle φ_k(a) changes according to (23), so that the power of the subleading behavior of φ_k(a) no longer depends on the equation of state. As we will see in Sec. III, the subleading behavior of the squeezing angle will determine the slope of the growth of complexity in the superhorizon limit. The slope of the growth of the complexity, then, will depend on the equation of state until it reaches the threshold value w = -5/3, after which it becomes independent of the equation of state.

Perturbations for decelerating solutions w > -1/3 (β < 0) begin outside the horizon for sufficiently early times a ≪ 1. In general, the squeezing parameter grows when a mode is superhorizon, so the squeezing is growing at early times for decelerating solutions to (16) and (17),

r_k(a) \approx r_0 + \ln (a/a_0), \quad (24)

φ_k(a) \approx -\frac{\pi}{2} + \frac{k \eta_0}{|\beta|(\beta + 2)} a^{1/\beta}, \quad (25)

where we introduced a fiducial scale factor a_0 where the squeezing parameter takes the value r_k(a_0) = r_0. Notice that the squeezing solutions here again grow universally as ~ ln a for all equations of state. On the other hand, the subleading term in the solution for the squeezing angle depends on the equation of state through the coefficients and power of the scale factor depending on |β|.

Unlike for accelerating
the form
\( \phi \) expanding decelerating solutions is approximately \( \phi \) mode is superhorizon. Once the mode crosses the horizon, \( n \) power grow, so that solutions to (16) and (17) in this regime take
squeezing “freezes-in” and the squeezing angle begins to
tions (24) and (25) apply to all equations of state.

backgrounds, however, there is no “threshold” value of the equation of state beyond which the qualitative nature of the solution for the squeezing angle changes. Instead, the solutions (24) and (25) apply to all equations of state.

At late times, after the mode reenters the horizon, the squeezing “freezes-in” and the squeezing angle begins to grow, so that solutions to (16) and (17) in this regime take the form

\[
\begin{align*}
    r_k(a) &\approx r_*, \\
    \phi_k(a) &\approx k \eta_0 a^{1/|\beta|}
\end{align*}
\]

for some fixed value of the squeezing \( r_* \), determined by the value of the squeezing at horizon reentry.

Together, this behavior for early and late times is qualitatively similar to the solution for squeezing in a radiation-dominated expanding background discussed in [28]. In particular, in Fig. 2 we see that the numerical solutions for a wide range of equations of state of interest follow the qualitative behavior described above: squeezing grows initially as the mode begins outside of the horizon, then “freezes-in” after the mode reenters the horizon. The squeezing angle begins approximately constant for early times, then evolves after the mode reenters the horizon.

Finally, let us consider the marginal \( w = -1/3 \) case, which is neither accelerating nor decelerating. The scale factor in conformal time takes the form

\[ a(\eta) = a_0 e^{\eta/\eta_0}, \quad \eta_0 > 0, \quad -\infty < \eta < \infty. \]

The conformal Hubble parameter then becomes constant, \( \mathcal{H} = 1/\eta_0 \), so the equations of motion (13) and (14) become

\[
\begin{align*}
    \frac{dr_k}{d\eta} &= -\frac{1}{a} \cos(2\phi_k), \\
    \frac{d\phi_k}{d\eta} &= \frac{k \eta_0}{a} + \frac{1}{a} \coth(2r_k) \sin(2\phi_k).
\end{align*}
\]

Unlike the accelerating and decelerating backgrounds, however, a comoving mode for \( w = -1/3 \) stays fixed relative to the horizon and does not exit or reenter the horizon at early or late times. The nature of the solutions to (29) and (30) is then controlled by the quantity \( k \eta_0 \). For \( k \eta_0 \gg 1 \), the mode is inside the horizon, and the squeezing remains small and the squeezing angle is approximately fixed. These solutions will not be interesting to us because we are interested in solutions in which the squeezing is large and growing, which we will see correspond to growing complexity. For \( k \eta_0 \ll 1 \), the mode is outside the horizon, and the equations of motion (29) and (30) for the squeezing variables have the solution for \( a \gg 1 \),

\[
\begin{align*}
    r_k(a) &\approx \ln a, \\
    \phi_k(a) &\approx -\frac{\pi}{2} + \frac{1}{2} k \eta_0 + \frac{B}{a^2}.
\end{align*}
\]

where again \( B \) is a constant set by the initial conditions. As with previous superhorizon solutions, we see again that the squeezing parameter grows while the squeezing angle asymptotically approaches a constant, for \( a \gg 1 \). Note, however, that the constant in this limit is shifted slightly from \(-\pi/2\) for \( w = -1/3 \) by an amount \( -k \eta_0 \ll 1 \), which will have implications for the late-time behavior of the complexity.

B. Contracting backgrounds

Now we will consider contracting cosmological backgrounds with a fixed equation of state. The scale factor for a contracting universe with a fixed equation of state can be
written

\[ a(\eta) = \left( \frac{\eta_0}{\eta} \right)^{\beta} = \begin{cases} \left( \frac{\eta_0}{\eta} \right)^{\beta}, & 0 < \eta < \infty, \ \eta_0 > 0 \text{ for accelerating backgrounds } \beta > 0 \ (w < -1/3), \\ \left( \frac{\eta}{\eta_0} \right)^{\beta}, & -\infty < \eta < 0, \ \eta_0 < 0 \text{ for decelerating backgrounds } \beta < 0 \ (w > -1/3), \end{cases} \]

as solutions for accelerating backgrounds have large squeezing \( r_k \gg 1 \) and take the form

\[ r_k \approx r_0 - \beta \ln \left( \frac{\eta}{\eta_0} \right) = r_0 - \ln a, \]

\[ \phi_k \approx \left( \frac{k}{1 + 2\beta} \right) \eta = \left( \frac{k \eta_0}{1 + 2\beta} \right) a^{-1/\beta}. \]

After the mode reenters the horizon as the universe contracts, the squeezing parameter “freezes-in,” as it did for the expanding decelerating solutions

\[ r_k \approx r_*, \]

\[ \phi_k \approx k \eta = k \eta_0 a^{-1/\beta}, \]

where \( r_* \) is the value of the squeezing parameter at the horizon crossing. The numerical solutions of (36) and (37) shown in the left panel of Fig. 3 for several accelerating equations of state \( w < -1/3 \) also illustrate this “freeze-in” behavior for the squeezing parameter \( r_k \) (note that the horizontal axis starts at large values of the scale factor on the left, as is appropriate for a contracting universe).

For a contracting decelerating universe, a typical mode begins inside the horizon at early times \( a \gg 1 \ (\eta \to -\infty) \) and exits the horizon as the universe evolves. At early times, then, the solution for the squeezing variables will resemble that of the expanding accelerating universe,

\[ r_k \approx \frac{1}{2k} \frac{|\beta|}{\eta_0 a^{1/|\beta|}}, \]

\[ \phi_k \approx \frac{\pi}{4} + \frac{1}{4k} a^{-1/|\beta|}, \]

with small squeezing \( r_k \ll 1 \). Similarly, at late times \( a \ll 1 \) the mode is outside of the horizon, and the squeezing is large.
and growing, \( r_k \gg 1 \). As with the expanding universe, the dominant subleading behavior of the squeezing angle changes as the equation of state (equivalently the parameter \( \beta \)) crosses a “threshold” value. As a result, we have the solutions

\[
\begin{align*}
\phi_k & \approx \begin{cases} 
\frac{k}{1-2|\beta|} \eta & \text{for } \beta < -1/2 \\
\frac{B |\eta|}{1-2|\beta|} a^{1/|\beta|} - \frac{k |\eta|}{|\beta|} a^{1/|\beta|} \ln a & \text{for } -1/3 < w < 1 \end{cases} \\
B & = a^2 
\end{cases}
= - \ln a,
\end{align*}
\]

Again, the numerical solutions of (36) and (37) shown in the right panel of Fig. 3 for several decelerating equations of state agree with these solutions for the squeezing parameter \( r_k \), particularly at late times where the squeezing grows as \( \sim (-\ln a) \) as \( a \) decreases (again note that the horizontal axis has a decreasing scale factor as one moves to the right since we have a contracting background).

Finally, we will consider the marginal \( w = -1/3 \) background for completeness. The scale factor in conformal time takes the form

\[
a(\eta) = a_0 e^{\eta/\eta_0} = a_0 e^{-\eta/|\eta_0|}, \quad \eta_0 < 0, \quad -\infty < \eta < \infty. \tag{46}
\]

Just like the expanding case, the conformal Hubble parameter then becomes constant, \( H = -1/|\eta_0| \), therefore the equations of motion (13) and (14) become

\[
\frac{dr_k}{da} = -\frac{1}{a} \cos(2\phi_k), \\
\frac{d\phi_k}{da} = -\frac{k |\eta_0|}{3} + \frac{1}{a} \cosh(2r_k) \sin(2\phi_k),
\]

and a comoving mode for \( w = -1/3 \) stays fixed relative to the horizon and does not exit or reenter the horizon at early or late times. Once again, for \( k |\eta_0| \gg 1 \), the mode is inside the horizon, and the squeezing parameter is small and the squeezing angle is fixed, \( \phi_k \approx -\pi/4 \). For \( k |\eta_0| \ll 1 \), the mode is outside the horizon, and the equations of motion (47) and (48) for the squeezing variables have the solution at late times \( a \ll 1 \),

\[
\begin{align*}
r_k(a) & \approx -\ln a, \\
\phi_k(a) & \approx \frac{1}{2} k |\eta_0| + B a^2,
\end{align*}
\]

where again \( B \) is a constant set by the initial conditions. As the universe contracts, the squeezing is large and growing, and the squeezing angle approaches a small, nonzero constant.

### III. COMPLEXITY FOR THE SQUEEZED STATE

In the previous section, we saw that it is natural to describe the evolution of scalar cosmological perturbations as a two-mode squeezed vacuum state. Now we will investigate the complexity of the squeezed cosmological perturbations. For our quantum circuit, a natural reference state is the two-mode vacuum state \( |0 \rangle_{k,-k} \), while our target state will be the squeezed two-mode vacuum state \( |\Psi_{sq} \rangle_{k,-k} \) in (11). As in [5], we will express the reference and target states as Gaussian wave functions. In that direction, we first define a set of auxiliary “position” and “momentum” variables

\[
\hat{q}_k \equiv \frac{1}{\sqrt{2k}} (\hat{c}_k + \hat{c}_{-k}), \quad \hat{p}_k \equiv i \frac{1}{\sqrt{2k}} (\hat{c}_k - \hat{c}_{-k}), \tag{51}
\]

which are conjugate variables \( [\hat{q}_k, \hat{p}_k] = i\delta(k - k') \). Notice that the main difference between the “position” \( \hat{q}_k \) and the Fourier mode \( \hat{c}_k \) given in (6) is that the former is defined with respect to a raising operator of \( k \) instead of \( -k \).

The two-mode vacuum state’s wave function, defined by \( \hat{c}_k |0 \rangle_{k,-k} = 0 \), has the usual Gaussian form

\[
\psi_{\text{br}}(q_k, q_{-k}) = \langle q_k, q_{-k} |0 \rangle_{k,-k} = \left( \frac{k}{\pi} \right)^{1/4} e^{-\frac{1}{2} (q_k^2 + q_{-k}^2)}. \tag{52}
\]

To calculate the wave function corresponding to the squeezed state (11), we note that the following combination annihilates \( \langle \Psi_{sq} | \hat{c}_k \rangle_{k,-k} \):

\[
(\cosh r_k \hat{c}_k + e^{-2i\phi_k} \sinh r_k \hat{c}_k e^{i\phi_k} - B q_k |q_{-k} \rangle_{k,-k} = 0. \tag{53}
\]

Using this, we can calculate the “position-space” form of the wave function [27],

\[
\Psi_{sq}(q_k, q_{-k}) = \langle q_k, q_{-k} | \Psi_{sq} \rangle_{k,-k} \equiv e^{A(q_k^2 + q_{-k}^2) - B q_k q_{-k}} \cosh r_k \sqrt{1 - e^{-4i\phi_k} \tanh^2 r_k}, \tag{54}
\]

where the coefficients \( A \) and \( B \) are functions of the squeezing parameter \( r_k \) and squeezing angle \( \phi_k \),

\[
A = k \left( \frac{e^{-4i\phi_k} \tanh^2 r_k + 1}{e^{-4i\phi_k} \tanh^2 r_k - 1} \right), \\
B = 2k \left( \frac{e^{-2i\phi_k} \tanh r_k}{e^{-4i\phi_k} \tanh^2 r_k - 1} \right). \tag{55}
\]

This is the quantum target state we will consider when we compute complexity below, where the quantum system under consideration is the dynamics determined by the action (4). For computing complexity we will use Nielsen’s geometric method [12] and follow the approach of [5], which we will simply call the circuit complexity. For our quantum circuit we will use the vacuum as the reference state (52) and the two-mode squeezed state as the target state (54). By using the “geodesic” weighting, we obtain the following expression for
complexity $C$:
\[
C(k) = \frac{1}{2} \sqrt{\left( \ln \frac{\Omega_k}{\omega_k} \right)^2 + \left( \ln \frac{\Omega_{-k}}{\omega_{-k}} \right)^2 + \left( \tan^{-1} \frac{\Im \Omega_k}{\Re \Omega_k} \right)^2 + \left( \tan^{-1} \frac{\Im \Omega_{-k}}{\Re \Omega_{-k}} \right)^2},
\]
where $\Omega_k = -2A + B$, $\Omega_{-k} = -2A - B$, and $\omega_k = \omega_{-k} = k/2$. The inverse tangent term in the above expression is necessary when the frequency is complex, see [34], although we will find that it does not play an important role in the qualitative behavior of the complexity. Using (55) in (56) we can obtain relatively simple closed-form expressions for complexity for the general two-mode squeezed vacuum state relative to the unsqueezed vacuum [28],
\[
C = \frac{1}{\sqrt{2}} \sqrt{\ln \left| \frac{1 + e^{-2i\phi_k} \tanh r_k}{1 - e^{-2i\phi_k} \tanh r_k} \right|^2 + \left| \tan^{-1}(2 \sin 2\phi_k \sinh r_k \cosh r_k) \right|^2}. \tag{57}
\]
Different choices of the weighting function lead to similar looking expressions to (57) with slightly different numerical factors. For example, when a linear weighting function is used, the terms in (57) are not added in quadrature but are simply added together, with a coefficient a factor of $\sqrt{2}$ larger [28]. Since several different weighting functions agree on the general form of the complexity, but not on the numerical factor out front, we will regard the overall multiplicative factor of the complexity (57) as uncertain.

In the rest of this section, we will analyze the behavior of the complexity (57) as a function of the scale factor by inserting the solutions for the squeezing parameters $r_k(a), \phi_k(a)$ found in Sec. II for expanding and contracting backgrounds.

A. Complexity for expanding FLRW backgrounds

We start by analyzing (57) for expanding backgrounds. As noted in Sec. II, the qualitative nature of the solutions for the squeezing parameters depends on whether the FLRW background is accelerating or not.

For accelerating FLRW backgrounds, at early times, $a \ll 1$, the squeezing parameter is small, $r_k \ll 1$, and the squeezing angle is approximately constant, $\phi_k \approx -\pi/4$, as found in (18) and (19). In this limit the complexity (57) vanishes, $C \to 0$, for all accelerating equations of state.

At late times, $a \gg 1$, the squeezing parameter is now large and growing, and the squeezing angle has changed so that $\phi_k \approx -\pi/2$. In this limit, the first term in (57) dominates over the second, so the complexity is approximately
\[
C \approx \frac{1}{\sqrt{2}} \ln \left| \frac{1 + e^{-2i\phi_k} \tanh r_k}{1 - e^{-2i\phi_k} \tanh r_k} \right|. \tag{58}
\]
Since $r_k \gg 1$, $\tanh r_k \approx 1$ in (58). The dependence of (58) on the scale factor then primarily comes from the subleading behavior of the squeezing angle. Inserting the solutions (22) and (23) into (58), and recalling that $\beta = -2/(1 + 3w)$, we find that the complexity grows as $\sim \ln a$ at late times for all accelerating backgrounds,
\[
C \approx \begin{cases} 
\frac{-1 + \beta}{2} \ln a & + \text{const}, \\
\sqrt{2} \ln a - \sqrt{2} \ln (\ln a), & w = -5/3, \\
\sqrt{2} \ln a + \text{const}, & w < -5/3,
\end{cases}
\]
where the double-log for $w = -5/3$ arises from the $\ln \ln$ in subleading behavior of the squeezing angle (23). Note that the extremely late time limit of the threshold $w = -5/3$ solution approaches $\sim \sqrt{2} \ln a$. However, for even fairly large values of the scale factor $a \sim 10^{10}$ the double-log term is still approximately $\sim 10\%$ of the leading-order term, and it contributes less than $1\%$ only for extremely large values of the scale factor $a > 10^{200}$.

Putting the early and late time behaviors together, then, we expect that for accelerating FLRW backgrounds the complexity for a cosmological perturbation will be approximately zero until the mode exits the horizon. After the mode exits the horizon, the complexity grows linearly with $\ln a$ (equivalently the number of e-folds), with a slope given by (59). As discussed in [28], the complexity for this mode will continue to grow indefinitely until the cosmological background itself changes and becomes nonaccelerating. Unlike other studies of complexity, then, we find that the complexity does not reach a maximum value in a finite amount of time, but instead grows without bound. This appears to be the case for our system because the expanding background acts as a classical time-dependent source coupled to the cosmological perturbations, so that we do not have a closed system. Figure 4 shows numerical solutions of the complexity (57) for accelerating FLRW backgrounds with a fixed equation of state, where we see clearly the general qualitative behavior for the complexity described above. In [22], it was argued that this behavior for the complexity—a period of approximately constant

**FIG. 4.** The complexity for accelerating expanding solutions grows linearly with $\ln a$ at late times. The slope grows with a decreasing equation of state until $w = -5/3$, after which the slope saturates, so that the growth of complexity is bounded by $dC/dt \leq \sqrt{2}H$. 

033273-8
complexity followed by linear growth—is a characteristic of quantum chaos. Similar behavior for the complexity in an expanding de Sitter background was found already in [28], where it was argued that cosmological perturbations in a de Sitter background are chaotic. Here we extend this argument: based on the behavior of the complexity, cosmological perturbations in all expanding, accelerating backgrounds display characteristic signs of quantum chaos.

Quantum chaos in the context of the out-of-time-ordered correlator is often described by two parameters: the scrambling time and the Lyapunov exponent. Based on other work connecting complexity with the out-of-time-ordered correlator [22,34], we conjecture that the duration of the approximately constant part of complexity corresponds to the scrambling timescale, while the slope of the linear portion behaves as a Lyapunov exponent, although it would be interesting to study this connection further. From this conjectured relationship, we can propose some estimates for these parameters from our analysis.

For our cosmological perturbations, the complexity is constant (and approximately zero) until the modes exit the horizon; the horizon exit time thus sets the scale for the conjectured scrambling time. Horizon exit occurs when \( k \sim \mathcal{H}_\ell \), which corresponds to \( k |\eta_0| \sim \beta \; a^{1/\beta} \). The number of e-folds up to scrambling for a particular \( k \)-mode then becomes \( N_e^{\text{scram}} \sim \beta \ln(k|\eta_0|/\beta) \). The number of e-folds required for scrambling is maximized (for fixed \( k |\eta_0| \)) at \( \beta = \ln(k|\eta_0|) - 1 \). It would be interesting to study this further to see if there are physical consequences to such a “slow scrambler.” For de Sitter space \( w = -1 \), we have \( |\eta_0| = H_{dS}^{-1} \), where \( H_{dS} \) is the de Sitter Hubble constant. Taking the mode to have a Planck scale wavelength, the number of e-folds up to “maximum scrambling” (scrambling of all modes up to the Planck scale) are then bounded by

\[
N_e^{\text{scram}} \leq \ln \left( \frac{M_{pl}}{H_{dS}} \right). \tag{60}
\]

Interestingly, this is of the same order (up to a factor of 2) as the scrambling time for de Sitter space proposed in [30], which was also found in a study of the out-of-time-order correlator for de Sitter space in [31,32], suggesting evidence in favor of this conjectured relationship. It is also identical to the timescale of the recently proposed Trans-Planckian Censorship Conjecture (see [35,36], among others), since it is simply the timescale for a Planck-scale wavelength to exit the horizon. Translating the scrambling condition into cosmic time, the scrambling time is approximately

\[
l_{\text{scram}} \sim \begin{cases} t_0 \left[ \frac{k}{H_{dS}} \right]^{3(1+w)/(1+3w)} , & w \neq -1, \\ H_{dS}^{-1} \ln \left( \frac{k}{H_{dS}} \right), & w = -1, \end{cases} \tag{61}
\]

where \( t_0 \) is the typical age of the universe for equation of state \( w \). Again, we see that for de Sitter space our conjectured scrambling time (61) is of the same order (up to a factor of 2) as the scrambling times proposed in [30–32]. More generally, for \( w = -1/3 \), the conjectured scrambling time (61) vanishes, \( l_{\text{scram}} \rightarrow 0 \). Alternatively, for large negative equation of state \( w \rightarrow -\infty \) the conjectured scrambling time (61) goes to zero as \( |w|^{-3} \). The maximum complexity time is therefore somewhere in between, and is set by \( k |\eta_0| \).

Interestingly, the slope of the growth of complexity with \( \ln(a) \) changes at the “threshold” value of the equation of state \( w = -5/3 \). The importance of this is perhaps better seen by constructing the slope \( \lambda \) of the growth of the complexity with respect to cosmic time, which using (59) becomes

\[
\frac{d\mathcal{C}}{dt} \equiv \lambda \approx \begin{cases} -\frac{1}{2\pi} \frac{H}{2}, & -5/3 < w < -1/3, \\ \sqrt{2} H (1 - \frac{1}{\ln(a)}), & w = -5/3, \\ \sqrt{2} H, & w < -5/3, \end{cases} \tag{62}
\]

where \( H = \dot{a}/a \) is the Hubble parameter defined with respect to cosmic time. For equations of state less negative than \( w = -5/3 \) (including de Sitter space \( w = -1 \)), the slope of the complexity depends on the value of the equation of state, vanishing as we approach \( w \rightarrow -1/3 \), and increasing as the equation of state becomes more negative. For equations of state more negative than \( w = -5/3 \), the slope saturates to a fixed value \( \lambda \sim \sqrt{2} H \) independent of the equation of state. The behavior of the slope \( \lambda \) for expanding backgrounds is shown in the left panel of Fig. 5. The open dot for \( w = -5/3 \) in Fig. 5 reflects the slow convergence of the slope (62) for this threshold equation of state due to the double-log behavior found in (59). Notice that for backgrounds that obey the null energy condition, de Sitter has the largest slope so de Sitter space appears to be maximally chaotic (in the sense of having the steepest slope) among null energy condition satisfying backgrounds. A similar result for the Lyapunov exponent for de Sitter space in \((2 + 1)\) dimensions was found in the context of the out-of-time-order correlator [31]. Though it is unclear at the moment what the relationship is between the two very different approaches, it is intriguing that both give rise to very similar descriptions of quantum chaos in de Sitter space.

The behavior of the slope of the complexity (62) implies that the slope is bounded,

\[
\frac{d\mathcal{C}}{dt} \equiv \lambda \lesssim \sqrt{2} H. \tag{63}
\]

The saturation of the slope of complexity growth is similar to the bound on chaos [29] found for the out-of-time-ordered correlator. In particular, Ref. [29] conjectured that the Lyapunov exponent of the out-of-time-ordered correlator (OTOC) is bounded from above by the temperature

\[
\lambda_{\text{OTOC}} \leq 2\pi T \sim H. \tag{64}
\]

where we used the temperature of an expanding background \( T \sim H/2\pi \) [37]. Because of their similarity up to an \( O(1) \) factor, we conjecture that the bound on the slope of the complexity (63) is related to the bound on the Lyapunov exponent of the OTOC (64). Interestingly, this \( O(1) \) factor becomes precisely 1, in exact agreement with (64), if we do not “double-count” the +\( k \) and −\( k \) modes in (56), or alternatively use a linear weighting functional instead of the geodesic weighting we have chosen here. Since the precise weighting function and formulation of complexity are still in development, we will just note this minor difference in passing. Regardless of the precise numerical factor, it is interesting that our analysis independently derives the existence of a bound (63) on quantum chaos. It is puzzling why this saturation occurs at the equation of state \( w = -5/3 \). It
would be interesting to study this cosmological background further, despite it violating the null energy condition, to see if it has any other cosmological significance.

Let us now consider the behavior of complexity (57) for decelerating backgrounds \( w > -1/3 \). Recall that in contrast to accelerating backgrounds, modes begin outside the horizon for arbitrarily early times in decelerating backgrounds, and reenter the horizon at late times. At early times, then, the squeezing parameter is large, \( r_k \gg 1 \), and growing, as found in (24). For accelerating backgrounds the squeezing angle asymptotically approaches a constant in the superhorizon limit. In contrast, for decelerating backgrounds the squeezing drifts away from a constant as the universe expands, as found in (25),

\[
\phi_k(a) \approx -\frac{\pi}{2} + \frac{k \eta_0}{|\beta|(1 + 2)} a^{1/|\beta|}. \tag{65}
\]

The combination of large squeezing and \( \phi_k \approx -\pi/2 \) again implies that the complexity is large, so that the first term in (57) is larger than the second, and we have again

\[
C \approx \frac{1}{\sqrt{2}} \ln \left| \frac{1 + e^{-2i\phi_k} \tanh r_k}{1 - e^{-2i\phi_k} \tanh r_k} \right|. \tag{66}
\]

Inserting (65) into (66), and using the limit \( r_k \gg 1 \), the complexity in the early-time, superhorizon limit behaves as

\[
C \approx -\frac{1 + 3w}{2\sqrt{2}} \ln(a/a_s), \tag{67}
\]

where \( a_s \equiv |\beta|(2 + |\beta|)/k \eta_0 \) is a constant, which approximately sets the time of horizon reentry (notice that when \( a \approx a_s \), we have \( C \approx 0 \)). The coefficient of (67) is negative for decelerating solutions \( w > -1/3 \), so this implies that the complexity decreases as the universe expands as \( \sim -\ln a \), in contrast to accelerating backgrounds. In particular, we can write the slope \( \lambda \),

\[
\frac{dC}{dt} \equiv \lambda \approx -\frac{1 + 3w}{2\sqrt{2}} H. \tag{68}
\]

Notice that the slope of the decreasing complexity is unbounded from below as the equation of state increases, unlike accelerating backgrounds where the slope of the complexity saturated after the equation of state reached a threshold value. The slope of the decreasing complexity can be made arbitrarily negative for \( w \gg 1 \), so that there is no corresponding bound of the form (64) from below.

After the mode reenters the horizon, our analysis from Sec. II found that the squeezing parameter “freeze-in” at some large value \( r_k \gg 1 \), while the squeezing angle grows with time as \( \phi_k \sim a^{1/|\beta|} \). Correspondingly, the complexity (66) will oscillate about a fixed “freeze-in” value, but will not grow or decay. Figure 6 shows the complexity for numerical solutions to the squeezing equations of motion (16) and (17) for several equations of state corresponding to decelerating backgrounds, illustrating the decreasing complexity and “freeze-in” features discussed above, as well as the dependence of the slope on the equation of state. The panel on the left of Fig. 5 shows how the negative slope for decelerating
backgrounds matches up smoothly to the behavior of $\lambda$ for accelerating backgrounds, and is unbounded below.

Finally, let us briefly comment on the marginal case of $w = -1/3$. As found in the discussion around (31) and (32), the behavior of these modes depends on whether the mode is inside, $k \eta_0 > 1$, or outside, $k \eta_0 < 1$, the horizon. For modes inside the horizon, the squeezing is small and the squeezing angle is approximately fixed. From (57), the complexity is small oscillations. For modes outside the horizon, we have the solutions (31) and (32). Recall that the squeezing angle approaches a constant $C \sim \ln|k \eta_0^{-1}|/\sqrt{2} \gg 1$. Correspondingly, the slope at late times vanishes, $\lambda \approx 0$, which agrees with the $w \rightarrow -1/3$ limit of (62) and (68).

### B. Complexity for contracting solutions

As with expanding solutions, the qualitative nature of the behavior of the complexity (57) will depend on whether the contracting universe background is accelerating, $w < -1/3$, or decelerating, $w > -1/3$. Let us begin as before with the accelerating contracting backgrounds. Recall that early times for a contracting background will correspond to a large scale factor $a \gg 1$, while at late times the scale factor will be small, $a \ll 1$. At early times, a cosmological mode in an accelerating contracting background begins outside the horizon, with large and growing squeezing parameter $r_k \gg 1$ (38). The squeezing angle grows slowly on large scales as $\phi_k \approx k \eta_0/(2 \beta + 1) a^{-1/\beta}$, from (39). Using the approximation (58)

$$C \approx \frac{1}{\sqrt{2}} \ln \frac{1 + e^{-2i \phi_k} \tanh r_k}{1 - e^{2i \phi_k} \tanh r_k}$$

for the complexity again, the complexity for early-time (super-horizon) accelerating contracting backgrounds is

$$C \approx \frac{1}{\sqrt{2}} \ln \frac{\eta_0}{\eta} = -\frac{1 + 3w}{2 \sqrt{2}} \ln(a/a_*)$$

where $a_* = [k \eta_0/(2 \beta + 1)]^{1/\beta}$ is again a constant that arises as roughly setting the scale for horizon reentry. Since the scale factor is decreasing with time, the complexity is actually decreasing with time. As in the expanding case, we define the slope $\lambda$ of the complexity,

$$\frac{dC}{dt} = \lambda \approx \frac{1 + 3w}{2 \sqrt{2}} |H| < 0,$$

where we have again written $H = \dot{a}/a$, and we used absolute value bars since $H < 0$ for a contracting universe. Thus the slope is negative for accelerating backgrounds, $w < -1/3$, similar to the decelerating expanding backgrounds from the previous subsection. Notice again that when the complexity is decreasing, the slope is unbounded from below, and it becomes arbitrarily negative as the equation of state becomes arbitrarily negative. We do not expect an arbitrarily negative equation of state to describe our universe, however, so it is not clear what the physical consequences of this limit are.

As the modes reenter the horizon, the squeezing parameter “freezes-in,” $r_k \approx r_*$, and the squeezing angle begins to run, as found in (40) and (41). From (57), the complexity also “freezes-in” and the running squeezing angle causes it to oscillate about the freeze-in value, as seen in the numerical solutions shown in Fig. 7 for several accelerating equations of state.

In contrast to the expanding case, it turns out it is the decelerating $w > -1/3$ contracting backgrounds that will give rise to a growing complexity. At early times, the squeezing is small, $r_k \ll 1$, and the squeezing angle is approximately fixed, $\phi_k \approx \pi$. Correspondingly, the complexity (57) is also small, $C \ll 1$, while the modes are inside the horizon. However, at late times, $a \ll 1$, as the modes exit the horizon, the squeezing parameter begins to grow and the squeezing angle will asymptotically approach zero as found in (44) and (45), so that the complexity (57) also begins to grow. While the growth of the squeezing parameter (44) is universal, the behavior of the squeezing angle again depends on the equation of state (45). Inserting (44) and (45) into (58), the dependence of the complexity on the scale factor grows as $\sim \ln(1/a)$ at late times,

$$C \approx \left\{ \begin{array}{ll} \frac{1 + 3w}{2 \sqrt{2}} \ln(1/a) + \text{const}, & -1/3 < w < 1, \\ \frac{3w}{2 \sqrt{2}} \ln(1/a) + \frac{1}{\sqrt{2}} \ln(\ln(1/a)), & w = 1, \\ \sqrt{2} \ln(1/a) + \text{const}, & w > 1, \end{array} \right.$$

where we wrote the argument of the log as $(1/a)$ to emphasize that as the scale factor $a$ decreases (as the universe contracts), the complexity increases. As with the accelerating expanding backgrounds, the rate of growth of complexity in the late-time limit $a \ll 1$ depends on the equation of state. Putting the early- and late-time behaviors together, we see that the complexity for decelerating contracting backgrounds mirrors that of accelerating expanding backgrounds. At early times, when the mode is inside the horizon the complexity is small; after the mode exits the horizon the complexity grows linearly with $\ln(1/a)$ (as $a \rightarrow 0$), as in (72). Figure 8 shows numerical solutions of the squeezing equations of motion (36)
and (37) inserted into the complexity (57), and it demonstrates the growth of complexity as modes exit the horizon, and the dependence of the slope of complexity on the equation of state. As mentioned earlier for expanding solutions, this behavior for the complexity is a characteristic of quantum chaos, suggesting that decelerating contracting solutions display some of the essential features of quantum chaos.

While the complexity itself does not saturate, again it is the slope of the growth of complexity that saturates as the equation of state reaches a "threshold" value. In particular, the slope of the growth of complexity that saturates as the growth rates of complexity between expanding de Sitter backgrounds with a fixed equation of state $w$. We found in Sec. II that the behavior of the squeezing parameters follows the general behavior discussed in [28]: when a mode is inside the horizon, the squeezing is fixed, up to small oscillations, while the squeezing grows for modes outside the horizon. We then used this behavior of the squeezing parameters to compute the corresponding cosmological circuit complexity. The behavior of the complexity depends on whether the cosmological background is expanding or contracting, and whether that background is accelerating, $w > -1/3$, or decelerating, $w < -1/3$.

The cosmological complexity grows linearly with log $a$ when modes are outside the horizon for accelerating expanding backgrounds and decelerating contracting backgrounds. In our model we do not see a saturation in the complexity itself, although this may be due to the expanding background acting as a classical coupling to the effective frequency of the cosmological perturbation. The linear growth of complexity is a characteristic of a chaotic system, so we propose that cosmological perturbations are chaotic for these corresponding backgrounds. We independently uncovered a bound on the growth rate of complexity $dC/dt \leq \sqrt{2} |H|$, which we conjecture is related, up to $O(1)$ factors, to a bound on the Lyapunov exponent of the out-of-time-order correlator [29]. This bound is saturated for equations of state $w < -5/3$ for expanding backgrounds and $w > 1$ for contracting backgrounds. It is unclear what the independent physical significance of these "threshold" equations of state is, and it would be interesting to study this further. Expanding de Sitter space is "maximally chaotic" among backgrounds that satisfy the null energy condition, in the sense that it has the largest slope. Continuing in the language of quantum chaos, we conjecture the scrambling time as the time that a mode exits the horizon. For de Sitter space, we argue that the maximum conjectured scrambling time is $t_{\text{scramb}} \sim H_{\text{dS}}^{-1} \ln(M_{\text{pl}}/H_{\text{dS}})$ for small wavelength modes, or correspondingly the maximum number of e-folds up to scrambling is $N_{\text{scramb}} \sim \ln(M_{\text{pl}}/H_{\text{dS}})$. These estimates are in line with other estimates of the scrambling time for de Sitter space [30–32].

For decelerating expanding backgrounds, or accelerating contracting backgrounds, the complexity decays linearly with log $a$ when the mode is outside the horizon, until eventually "freezing-in" to a fixed value up to oscillations when the mode reenters the horizon. The slope of the decaying complexity is unbounded from below, so arbitrarily large equations of state ($|w| > 1$ with $w > 0$ for decelerating expanding backgrounds or $w < 0$ for accelerating contracting backgrounds) give rise to arbitrarily steep slopes, though it is unclear how physical are these backgrounds with extremely large equations of state. Additionally, if the mode is outside the horizon, it will remain outside the horizon; while the squeezing will grow, the complexity will remain constant because the squeezing angle also becomes constant at late times.
A number of interesting questions remain. We found a bound in the slope of the complexity that is similar to the bound in the Lyapunov exponent [29] coming from the out-of-time-ordered correlator (OTOC). It would be interesting to study the OTOC for our system to see directly if such a bound on the Lyapunov exponent exists, and if so, what mechanism ensures a separation of dissipation and scrambling timescales. In this and other recent work [28], we studied cosmological perturbations with sound speed equal to 1, corresponding to perturbations with an equation of state that differs from 1, and to perturbations with sound speed equal to 1, corresponding to contracting backgrounds. This behavior for the complexity could be signaling some amount of entanglement of the perturbations with the degrees of freedom on the horizon. In particular, an increasing complexity could be signaling increasing entanglement of the mode with the horizon as the mode stretches outside the horizon, while a decreasing complexity signals disentanglement as the mode reenters the horizon. It would be interesting to study this reasoning further. Finally, we note that in our model the complexity itself is unbounded, and it can continue to grow indefinitely for accelerating expanding backgrounds. Perhaps there are other physical limits in our system that bound the complexity and prevent it from becoming arbitrarily large, in line with other expectations on the behavior of complexity. These and other interesting questions we leave to future work.

APPENDIX: INTERMEDIATE BEHAVIOR OF COMPLEXITY

In the investigation of the solutions to the squeezing equations of motion (16) and (17) for accelerating expanding backgrounds \( \beta > 0 \) in Sec. II, we found that the subleading behavior of the squeezing angle \( \phi_1 \) on superhorizon scales and late times \( a \gg 1 \) contained a combination of homogeneous and inhomogeneous solutions,

\[
\phi_1 \approx -\frac{\pi}{2} + \frac{k|\eta_0|}{2\beta - 1}\frac{1}{a^{3/\beta}} + \frac{B}{a^2}, \quad \beta > 1/2, \quad (A1)
\]

where \( B \) is a constant set by the initial conditions. As argued there, for \( \beta > 1/2 \) the inhomogeneous term dominates at late times \( a \gg 1 \), while for \( \beta < 1/2 \) the homogeneous term dominates \( [\beta = 1/2 \) is a special case, and is considered in more detail in the discussion above (22)]. The dominant subleading behavior of the squeezing angle is important because it determines the late-time slope of the growing complexity, as we saw in Sec. III. The transition to the homogeneous term as \( \beta < 1/2 \) leads to the saturation of the slope of complexity \( dC/da \leq \sqrt{2}H \).

However, for \( \beta > 1/2 \) occasionally the combination of the initial conditions set by \( B \), and the coefficient on the inhomogeneous term in (A1), can be such that the homogeneous term temporarily dominates over the inhomogeneous term in an intermediate regime. This intermediate regime occurs after the mode has exited the horizon, but at still relatively early times. The subleading behavior of the squeezing angle thus behaves as \( \phi_1 = -\pi/2 + B/a^2 \) even for \( \beta > 1/2 \), in this intermediate regime. After a sufficiently long amount of time, however, the inhomogeneous term in (A1) begins to dominate again, with the transition between the two behaviors occurring at

\[
\frac{k|\eta_0|}{2\beta - 1}\frac{1}{a^{3/\beta}} \approx \frac{B}{a^2}. \quad (A2)
\]

After this transition, the squeezing angle is again dominated by the inhomogeneous term at late times for \( \beta > 1/2 \).

This transition in behavior for the squeezing angle leads to a corresponding change in the slope of the growing complexity. At early times, when the mode is within the horizon, the complexity is still small. When the mode is in the intermediate regime identified above, however, the slope is now set by the homogeneous term

\[
C \approx \sqrt{2} \ln(a), \quad (A3)
\]

which saturates the general limit (63). After the transition, however, the slope changes to the (smaller) inhomogeneous value at late times,

\[
C \approx -\frac{1 + 3w}{2\sqrt{2}} \ln(a) \quad (A4)
\]

(recall that \(-1/3 < w < -5/3 \) for \( \beta > 1/2 \), so the coefficient above is positive). This leads to a “break” in the slope of the complexity, as shown in Fig. 9, which we recognize as simply
a transition between the inhomogeneous and homogeneous solutions for the squeezing angle (A1). Despite this minor caveat, the late-time slopes identified in (62) are correct since they are taken sufficiently late that only the asymptotic behavior $a \gg 1$ is important. A similar effect also occurs for the squeezing angle on decelerating contracting backgrounds, but it is identical in nature so we will not consider it in detail further.
