Abstract

This paper presents a novel approach for approximate integration over the uncertainty of noise and signal variances in Gaussian process (GP) regression. Our efficient and straightforward approach can also be applied to integration over input dependent noise variance (heteroscedasticity) and input dependent signal variance (nonstationarity) by setting independent GP priors for the noise and signal variances. We use expectation propagation (EP) for inference and compare results to Markov chain Monte Carlo in two simulated data sets and three empirical examples. The results show that EP produces comparable results with less computational burden.

1 Introduction

Gaussian processes (GP, Rasmussen and Williams, 2006) are commonly used as flexible non-parametric Bayesian priors for functions. They provide an analytical framework that can be applied to various probabilistic learning tasks, for example, in geostatistics, gene expression time series (Hensman et al., 2013), and density estimation (Riihimäki and Vehtari, 2014). A typical assumption is that the parameters of the GP model stay constant over the input space. However, this is not reasonable when it is clear from the data that the phenomenon changes over the input space (see, e.g., Silverman, 1985).

As an improvement to these cases, Goldberg et al. (1997) proposed heteroscedastic noise inference for Gaussian processes using a second GP to infer the log noise variance and doing the inference by Markov
chain Monte Carlo (MCMC). More recent work on heteroscedastic noise models include solving the problem by transformation of the mean and variance parameters to natural parameters of Gaussian distribution (Le et al., 2005), considering a two-component noise model (Naish-Guzman and Holden, 2007), and an expectation maximization like algorithm (Kersting et al., 2007). Adams and Stegle (2008) used expectation propagation (EP, Minka, 2001a,b) to the model input-dependent signal variance (signal magnitude) in GPs by factoring the output signal to a product of a strictly positive modulating signal and a non-restricted signal, with independent GP priors for both of the signals.

Non-stationarity can also be incorporated to the length-scales as proposed by Gibbs (1997) and further developed by Paciorek and Schervish (2004), where both used MCMC for the approximative inference. In general, the length-scale and the signal variance of a GP are underidentifiable and the proportion of them is more important to the predictive performance (Diggle et al., 1998; Zhang, 2004; Diggle and Ribeiro, 2007). Therefore, we assume that a GP with input-dependent signal variance and a GP with input-dependent length-scale would produce similar predictions. Thus, in this paper we concentrate on the input-dependent signal variance.

In this work, we present a straightforward and fast approach to integration over the uncertainty of the noise and signal variance in GP regression using EP. This approach can also be applied to input-dependent noise and signal variance by giving them independent GP priors. We extend the heteroscedastic noise model by Goldberg et al. (1997) to EP inference, and extend the nonstationary model by Adams and Stegle (2008) to analytical predictions. We consider the joint posterior of the modulating signal and the non-restricted signal variance by giving them independent GP priors. We extend the heteroscedastic noise and signal variance in GP regression using EP. This approach can also be applied to input-dependent signal variance and a GP with input-dependent length-scale would produce similar predictions. Thus, in this paper we concentrate on the input-dependent signal variance.

In standard GP regression the output \( y \) is modeled as a function \( f \) plus some additive noise \( \epsilon \) such that \( y(x) = f(x) + \epsilon \). If \( \epsilon \sim \mathcal{N}(0, \sigma^2) \), \( y \) can be expressed as

\[
y(x) \sim \mathcal{N}(f(x), \sigma^2).
\]

The function \( f \) is given a Gaussian process prior,

\[
f(x) \sim \mathcal{GP}(m(x), k(x, x')),
\]

defined by its mean and covariance functions. In this work we use zero mean Gaussian processes for nontational convenience. As for the covariance function, we use the common squared exponential (exponential quadratic):

\[
k(x, x') = \sigma^2 \exp \left( -\sum_{i=1}^{d} \frac{(x_i - x'_i)^2}{2\ell^2_i} \right),
\]

where \( x, x' \in \mathbb{R}^d \), \( \sigma^2 \) is the magnitude or signal variance of the covariance function and \( \ell_i \) is the characteristic length-scale corresponding to the \( i \)th input dimension.

Given a data matrix \( X = [x_1, x_2, \ldots, x_n] \), we can write our GP prior for the latent function \( f(x) = \mathbf{f} \) as

\[
\mathbf{f} \sim \mathcal{N}(0, K(X, X)) = \mathcal{N}(0, \mathbf{K}_f).
\]
From now on handle the positive restriction. We use the squared set the GP prior for the logarithm of the variances to
nals:
and the observation is combination of the three sig-

tral likelihood terms with Gaussian site approxima-
tically. EP forms a Gaussian approximation to the
posterior distribution cannot be computed analyti-
cally in most cases, because the likelihood function
observation is combination of the three sig-
s
log(σ^2(x)) ~ \mathcal{GP}(m(x), k_n(x,x')),
log(σ_f^2(x)) ~ \mathcal{GP}(m(x), k_m(x,x')).
(5)

From now on θ = log(σ^2(x)) and φ = log(σ_f^2(x)). We
set the GP prior for the logarithm of the variances to
handle the positive restriction. We use the squared exponential covariance function also for k_n(x,x') and
k_m(x,x'), although other covariance functions could
be used as well.

3 Approximate Inference
In this section we go through the EP approximation,
different models we use, and the algorithmic details.

3.1 Expectation Propagation
Expectation propagation is a general algorithm for
forming an approximating distribution (from the ex-
ponential family) by matching the marginal moments
of the approximating distribution to the marginal moments of the true distribution (Minka, 2001a,b).
The notation in this section follows mainly the nota-
tion of Rasmussen and Williams (2006).

With Gaussian processes we wish to form the pos-
terior distribution of the latent variables f given the
observations and inputs p(f | X,y). However, the
posterior distribution cannot be computed analyti-
cally in most cases, because the likelihood function
and the prior distribution cannot be combined ana-
ytically. EP forms a Gaussian approximation to the
posterior distribution by approximating the indepen-
dent likelihood terms with Gaussian site approxima-
tions t_i. This enables the analytical computation of
the posterior distribution because both the likelihood
approximation and the prior are Gaussian:

\[ p(y_i \mid f_i) \approx \tilde{Z}_i \tilde{t}_i(f_i) = \tilde{Z}_i N(f_i \mid \tilde{\mu}_i, \tilde{\Sigma}_i), \]
(6)

where \( \tilde{Z}_i, \tilde{\mu}_i \) and \( \tilde{\Sigma}_i \) are the parameters of the site
approximations, or site parameters. We use EP to
approximate the posterior of f such that

\[ p(f \mid X, y) = \frac{1}{Z_{EP}} p(f \mid X) \prod_i p(y_i \mid f_i) \]
\[ \approx \frac{1}{Z} p(f \mid X) \prod_i \tilde{t}_i(f_i) = q(f \mid X,y), \]
(7)

where Z is the normalization constant or marginal
likelihood, Z_{EP} is the EP approximation to the
marginal likelihood, p(f | X) is the prior of the latent
variables f, and q(f | X,y) is the Gaussian approxi-
mation to the exact posterior distribution p(f | X,y).

3.2 Noise Variance
To integrate over the uncertainty of the noise vari-
ance in GP regression, we approximate the Gaussian
likelihood as a product of two independent Gaussian
site approximations \( t_i \) for the mean \( f_i \) and for
the logarithm of the noise variance \( \theta \):

\[ p(y_i \mid f_i, \sigma^2) = N(y_i \mid f_i, \sigma^2) = N(y_i \mid f_i, e^{\theta}) \]
\[ \approx \tilde{Z}_i \tilde{t}_i(f_i) \tilde{t}_i(\theta). \]
(8)

The posterior approximation of the latent variables f
and θ can now be written in a factorized form, if we
set an independent prior distributions for f and θ

\[ p(f, \theta \mid X,y) \approx q(f \mid X,y) q(\theta \mid X,y). \]
(9)

3.3 Signal Variance
If we wish to use the same approach as for noise vari-
ance to also integrate over the uncertainty of the sig-
nal variance, we need to move the signal variance
from the GP prior to the likelihood function. Oth-
ervise we would need to integrate over an n-by-n
matrix determinant, which is computationally expen-
sive. To move the signal variance to the likelihood
function, we reparameterize f as \( f = \sigma_f \tilde{f} \), where \( \sigma_f \)
is the square root of the signal variance. Now, if
Cov[f] = σ_f^2 K, then Cov[\hat{f}] = K, where K is covariance matrix computed with identity signal variance in (3). As noted in Section 2, we model the logarithm of the signal and noise variances to take into account the restriction for them to be positive. Because both of the signal and noise variances to take into account variance matrix computed with identity signal variance of doing a factorized approximation as for the noise variance, we approximate the likelihood with two site approximations: one for the noise variance and a joint two-dimensional Gaussian for \( v_i = (\tilde{f}_i, \phi) \):

\[
p(y_i \mid \tilde{f}_i, \phi) = N(y_i \mid e^{\phi/2} \tilde{f}_i, e^\phi)
\approx \tilde{Z}_i \tilde{t}_i(\tilde{f}_i, \phi) \tilde{t}_i(\theta).
\]  

Assuming independent priors for the latent variables \( \tilde{f}, \phi \) and \( \theta \), the posterior approximation is also analogous to the noise variance case, such that

\[
p(\tilde{f}, \phi \mid X, y) \approx q(\tilde{f}, \phi \mid X, y) q(\theta \mid X, y).
\]

It should be noted that we also tested the fully factorized approximation \( \tilde{t}_i(\tilde{f}_i, \phi) = \tilde{t}_i(f_i) \tilde{t}_i(\phi) \), but it gave worse predictions, and the EP algorithm needed clearly more iterations to converge.

### 3.4 Input-Dependent Noise and Signal Variance

We can easily extend the presented likelihood approximations to also include input-dependency on signal and noise variances (or either one), by setting independent GP priors for both the logarithm of the noise variance and logarithm of the signal variance:

\[
p(\theta \mid X) = N(0, K_\theta),
p(v \mid X) = N(0, K_v).
\]

If we integrate over the input-dependent signal variance, we have

\[
K_v = \begin{bmatrix} K_\tilde{f} & 0 \\ 0 & K_\phi \end{bmatrix},
\]

otherwise we have \( K_v = K_\tilde{f} \). The covariance matrices are computed from the squared exponential covariance function (3). By setting the GP priors, we assume that the signal and noise variances are also some unknown functions that depend on the input \( x \).

The site approximations are of the same form independent of the input-dependency of the parameters

\[
\tilde{t}_i(\theta_i) = N(\tilde{\mu}_{\theta,i}, \tilde{\Sigma}_{\theta,i}),
\tilde{t}_i(v_i) = N(\tilde{\mu}_{v,i}, \tilde{\Sigma}_{v,i}).
\]

If we integrate over the (input-dependent) signal variance, we have

\[
\tilde{\mu}_{v,i} = \begin{bmatrix} \tilde{\mu}_{f,i} \\ \tilde{\mu}_{\phi,i} \end{bmatrix} \text{ and } \tilde{\Sigma}_{v,i} = \begin{bmatrix} \tilde{\Sigma}_{f,i} & \tilde{\Sigma}_{f,\phi,i} \\ \tilde{\Sigma}_{\phi,f,i} & \tilde{\Sigma}_{\phi,i} \end{bmatrix},
\]

otherwise \( \tilde{\mu}_{v,i} = \tilde{\mu}_{f,i} \) and \( \tilde{\Sigma}_{v,i} = \tilde{\Sigma}_{f,i} \). Here we have used \( \Sigma \) for both the scalar variance of the univariate Gaussian and the covariance matrix of the bivariate Gaussian, but it should be clear from the context which one it represents.

The posterior distributions can be computed with

\[
q(\nu \mid X, y) = N(\tilde{\mu}_v, \Sigma_v) \propto p(\nu \mid X) \prod_i \tilde{t}_i(v_i)
\]

\[
= N(\nu \mid 0, K_v)N(\nu \mid \tilde{\mu}_v, \Sigma_v),
\]

\[
q(\theta \mid X, y) = N(\tilde{\mu}_\theta, \Sigma_\theta) \propto p(\theta \mid X) \prod_i \tilde{t}_i(\theta_i)
\]

\[
= N(\nu \mid 0, K_\theta)N(\theta \mid \tilde{\mu}_\theta, \Sigma_\theta),
\]

where \( \tilde{\mu}_\theta = \Sigma_v \Sigma_\theta^{-1} \mu_\theta \) and \( \Sigma_v = (K_v^{-1} + \Sigma_\theta^{-1})^{-1} \). The joint site covariance \( \Sigma_v \) is diagonal while \( \Sigma_v \) has a block form if we integrate over the input-dependent signal variance

\[
\Sigma_v = \begin{bmatrix} \tilde{\Sigma}_{f} & \tilde{\Sigma}_{f,\phi} \\ \tilde{\Sigma}_{\phi,f} & \tilde{\Sigma}_{\phi} \end{bmatrix},
\]

where each block is diagonal. Cross-diagonal terms, \( \tilde{\Sigma}_{f,\phi} = \tilde{\Sigma}_{f,\phi} \) collect the marginal covariances \( \tilde{\Sigma}_{f,\phi,i} \) and the main-diagonal terms, \( \tilde{\Sigma}_f \) and \( \tilde{\Sigma}_\phi \), collect the marginal variances \( \tilde{\Sigma}_{f,i} \) and \( \tilde{\Sigma}_{\phi,i} \). If we do not integrate over the signal variance, we have \( \tilde{\Sigma}_v = \tilde{\Sigma}_f \).

### 3.5 EP Algorithm

The full EP algorithm is presented in Algorithm 1.

The main points in the algorithm are the same as
in the standard EP approach for Gaussian processes (Rasmussen and Williams, 2006, pp. 52–60). However, there are some implementation details that should be noted:

1. The overall stability of the EP updates can be improved by working in the natural parameter space of the site approximations. This means that we use the natural parameterization, \( \hat{v} = \hat{\Sigma}^{-1} \mu \) and \( \hat{\tau} = \hat{\Sigma}^{-1} \), for the site approximations. This way we can avoid inverting the site covariance matrices at every iteration.

2. Even though the algorithm should be stable and robust, there are some cases where the site updates exhibit oscillations, for example, due to weird hyper-parameter values in the covariance functions. Thus, the updates should be damped after computing the new site approximations in step 4,

\[
\Delta \tau_i = \delta (\tau_i^{\text{new}} - \tau_i^{\text{old}}), \quad \Delta \nu_i = \delta (\nu_i^{\text{new}} - \nu_i^{\text{old}})
\]

\[
\tau_i^{\text{new}} = \tau_i^{\text{old}} + \Delta \tau_i, \quad \nu_i^{\text{new}} = \nu_i^{\text{old}} + \Delta \nu_i,
\]

with some suitable damping factor \( \delta \), for example \( \delta = 0.8 \).

3. In step 3 of the algorithm we minimize KL divergence with respect to Gaussian distributions. This means that we match the first and second moments of the one-dimensional distributions and in addition to these the cross-moments if we have a bivariate Gaussian \( \hat{I}_i(v) \). The integrals over \( f_i \) or \( \hat{f}_i \), can be computed analytically in every case in steps 2 and 3. If we don’t integrate over signal variance, this can be done trivially as both the cavity and likelihood are Gaussian with respect to \( f_i \). If we integrate over signal variance, we can use the standard factorization of the multivariate Gaussian 

\[
q_{-i}( \hat{f}_i, \phi_i ) = q_{-i}( \hat{f}_i | \phi_i ) q_{-i}( \phi_i )
\]

The integrals over \( \theta \) and \( \phi \) must be computed numerically, but this can be done effectively, for example, with Simpson’s method.

4. We use parallel EP updates for the site parameters. This means that we compute the site updates for every site approximations before we update the posterior distribution and compute the marginal likelihood. This usually results in a few more EP iterations than sequential EP, but the overall speed of the algorithm is faster.

### Algorithm 1 Parallel EP algorithm

1. Initialize \( \hat{\mu}_{i,\theta} = \hat{\mu}_{i,v} = \hat{\Sigma}^{-1} = \hat{\Sigma}^{-1} = 0 \) for \( i = 1, 2, \ldots, n \). Set \( q(\theta \mid X, Y) = p(\theta \mid X) \) and \( q(v \mid X, Y) = p(v \mid X) \).

2. Compute the normalization \( \hat{Z}_i \):

\[
\hat{Z}_i = \int \int p(y_i \mid v_i, \theta) q_{-i}(v_i)q_{-i}(\theta) \, dv_i \, d\theta
\]

3. Find the best marginal posterior approximation for \( q_{i}(v_i) \) and \( q_{i}(\theta) \) by

\[
\min_{q_{i}(v_i)} \text{KL}(\hat{Z}_i^{-1} p(y_i \mid v_i, \theta)q_{-i}(v_i)q_{-i}(\theta) \parallel q_{i}(v_i))
\]

\[
\min_{q_{i}(\theta)} \text{KL}(\hat{Z}_i^{-1} p(y_i \mid v_i, \theta)q_{-i}(v_i)q_{-i}(\theta) \parallel q_{i}(\theta)).
\]

4. Update the site approximations \( \hat{I}_i \) by

\[
\hat{I}_i(v_i) \propto q_i(v_i)/q_{-i}(v_i)
\]

\[
\hat{I}_i(\theta) \propto q_i(\theta)/q_{-i}(\theta)
\]

analogously to step 1.

5. Update the posterior distributions with (16)–(17).

6. Compute the marginal likelihood with (22).

until Convergence

#### 3.5.1 Marginal Likelihood

Marginal likelihood can be used for model selection under GP framework as it has good calibration and the maximum of the marginal likelihood usually corresponds to good predictions (Rasmussen and Williams, 2006; Nickisch and Rasmussen, 2008; Ri-
ihimäki et al., 2013). Marginal likelihood in Gaussian processes is defined as

\[ Z = p(y \mid X) = \int p(f \mid X)p(y \mid f)\,df. \quad (19) \]

For our noise and signal variance GPs, an EP approximation to the marginal likelihood is

\[ Z \approx Z_{EP} = q(y \mid X) \]

\[ = \int p(v \mid X)p(\theta \mid X)\prod_i Z_i(v_i)\,dv\,d\theta, \quad (20) \]

where \( v = (\tilde{f}, \phi) \) or \( v = f \). Following Cseke and Heskes (2011), we define the term

\[ \log Z(m, V) = \frac{1}{2}m^TV^{-1}m + \frac{1}{2}\log|V| + \frac{n}{2}\log(2\pi). \quad (21) \]

Now the EP approximation for marginal likelihood can be computed with

\[ \log Z_{EP} = \log Z(\mu_\theta, \Sigma_\theta) + \log Z(\mu_v, \Sigma_v) \]

\[ + \sum_i (\log Z(\mu_{-i, \theta}, \Sigma_{-i, \theta}) - \log Z(\mu_i, \Sigma_i)) \]

\[ + \sum_i (\log Z(\mu_{-i, v}, \Sigma_{-i, v}) - \log Z(\mu_i, \Sigma_i)) \]

\[ - \log Z(0, K_v) - \log Z(0, K_\theta) + \sum_i \log Z_i, \quad (22) \]

where \( \mu \) and \( \Sigma \) are the parameters of the posterior distribution approximation \( q(\cdot \mid X, y) \), \( \mu_i \) and \( \Sigma_i \) are the \( i \)th marginal terms of \( \mu \) and \( \Sigma \), \( \mu_{-i} \) and \( \Sigma_{-i} \) are the \( i \)th marginal mean and variance parameters of the cavity distributions \( q_{-i}(\cdot) \), and \( K_f \) are the prior covariances from the GP.

Note that for \( \theta \) the marginal parameters are one-dimensional, but for \( v \) they are two-dimensional if we integrate over the signal variance like for the site approximations in (15).

### 3.5.2 Predictions

For predicting a future observation \( y^* \) for input \( x^* \), we need to compute the predictive distribution

\[ p(y^* \mid x^*, X, y) = \int\int p(y^*, v^*, \theta^* \mid x^*, X, y)\,dv^*\,d\theta^* \]

\[ = \int\int p(y^* \mid v^*, \theta^*)q(v^* \mid x^*, X, y)q(\theta^* \mid x^*, X, y)\,dv^*\,d\theta^*, \quad (23) \]

where

\[ q(v^* \mid x^*, X, y) = \int p(v^* \mid v)q(v \mid X, y)d\mathbf{f} \quad (24) \]

can be easily computed using properties of Gaussian processes. Note that if we assume stationary signal or noise variance, the respective posterior distributions reduce to one-dimensional Gaussian distributions. This means that \( q(v \mid X, y) \) becomes \( n + 1 \)-dimensional, and the posterior predictive distribution equals the posterior distribution. Because we approximate the posterior predictive distribution of the latent variables and the predictive distribution of \( y^* \) by a Gaussian distribution, we can always compute the predictions analytically, regardless whether we have input-dependent signal or noise variance. For a GP with EP marginalized noise variance we get the following predictive distributions

\[ \mathbb{E}[y^* \mid x^*, X, y] = \mathbb{E}[f^* \mid x^*, X, y] \quad (25) \]

\[ \mathbb{V}[y^* \mid x^*, X, y] = \mathbb{V}[f^* \mid x^*, X, y] \]

\[ + \exp(\mathbb{E}[^* \mid x^*, X, y] + \frac{1}{2} \mathbb{V}[\theta^* \mid x^*, X, y]). \quad (26) \]

For a GP with EP marginalized noise and signal variance the results are quite lengthy and are omitted here to save space (see supplementary material).

### 3.5.3 Factorized Approximation and Convergence

In this section we discuss certain key properties of the posterior approximations introduced in Sections 3.2-3.4. More precisely, we illustrate the importance of the utilized factorization assumptions in terms of both accuracy and convergence of the resulting EP algorithm.
Figure 1: Example comparisons of EP posterior approximations with MCMC samples from the latent posterior and the convergence of the EP algorithm. Red contours correspond to the factorized approximation $q(\tilde{f}, \phi)q(\theta)$ introduced in Section 3.4 (blue contours) and a fully factorized approximation of the form $q(\tilde{f})q(\phi)q(\theta)$ (red contours). Subplots on the left show strong posterior dependencies between the latent values resulting from the combined effect of the within-observation couplings $f_i = \tilde{f}_i \exp(\phi_i/2)$ and the between-observation correlations controlled by the GP priors. On the other hand, subplots on the right show much weaker couplings indicating that the the within-observation coupling does not necessarily introduce strong posterior dependencies. Comparison of the joint posterior approximations of $\theta_i$ with either $\phi_i$, $\tilde{f}_i$, or $f_i = \tilde{f}_i \exp(\phi_i/2)$ did not show strong dependencies, which is why we used a factorized approximation for $\theta$ to facilitate computations.

According to our experiments, neglecting the posterior couplings does not significantly affect the predictive performance compared to the fully-factorized approximation. However, representing these couplings has a significant effect on the convergence properties of the EP algorithm. Subfigure (b) of Figure 1 shows the EP marginal likelihood approximations as a function of EP iteration in both settings. The fully-coupled approximation (red line) converges very slowly compared to the partially coupled approximation (blue line); the former requires often hundreds of iterations whereas the partially-coupled approach converges usually in less than 50 iterations. In our experiments the convergence properties of the full-coupled algorithm could not be improved by adjusting damping.

This behavior can be explained by slow propagation of information between the latent values from different likelihood terms with the fully-coupled approximation. Because each likelihood term is updated separately from the others, information on the posterior dependencies in other site terms is not available during the update. These findings are fully congruent with the convergence differences in multi-class GP classification when between-class dependencies
are omitted (Riihimäki et al., 2013).

4 Experiments

In this section we go through the different data sets we use for experiments, different methods and the assessment criteria for the results.

Simulated data 1. The first simulated data was generated by the following setup:

\[
\hat{f}(x) = \sin(x),
\]

\[
\sigma_f(x) = N(x \mid -2.5, 1) + N(x \mid 2.5, 1),
\]

\[
\sigma(x) = 0.08 + N(x \mid -8, 3) + N(x \mid 8, 3),
\]

\[
y(x) = \sigma_f(x) \hat{f}(x) + \epsilon,
\]

(27)

where \(\epsilon \sim N(0, \sigma(x))\). The training data was generated by first drawing 200 random \(x\) values from \(U(-8, 8)\). After this we computed the mean signal by combining the modulating signal \(\sigma_f(x)\) and \(\hat{f}(x)\). Then some random noise with standard deviation \(\sigma(x)\) was added. For the test set we used uniform grid of 1000 points in the interval \((-8, 8)\) and computed the function values analogously to training set, without adding noise. The experiment was repeated 100 times for different realizations of the training data set to assess the variation in the final predictions of the test set.

Simulated data 2. The second simulated dataset was generated with

\[
\hat{f}(x) = \sin(x),
\]

\[
\sigma_f(x) = \exp(2 \sin(0.2x)),
\]

\[
\sigma(x) = \exp(0.75 \sin(0.5x + 1)) + 0.1,
\]

\[
y(x) = \sigma_f(x) \hat{f}(x) + \epsilon,
\]

(28)

The training and test data were generated analogously to the first experiment. We used 150 training points and the different generating signals for the observations. The second experiment was also repeated 100 times as in the first experiment.

Motorcycle. The motorcycle data (Silverman, 1985) consists of 133 accelerometer readings in a simulated motorcycle crash.

Concrete. The second empirical experiment uses concrete quality data (Vehtari and Lampinen, 2002; Jylänki et al., 2011), where the output is volume percentage of air in concrete, air-%, with 27 different input variables. The input variables depend on the properties of the stone materials, additives and the amount of cement and water.

SP500. The last empirical experiment is concerned with predicting the SP500 index. The data set consists of monthly averages of the index between years 2001–2014, with a total of 169 observations. We demonstrate on this data how a GP with input-dependent noise variance works as a stochastic volatility model.

We compare 8 different methods: GP (Standard GP regression), EP(n) and MCMC(n) (integration over input-dependent noise variance with EP and MCMC), EP(n+m) and MCMC(m+n) (integration over input-dependent signal and noise variance with EP and MCMC), EP-MC(n) and EP-MC(m+n) (EP optimized hyperparameters for covariance functions and sampling of the posterior of the latent variables).

Figure 2 presents the behaviour of the EP \((m+n)\) for the one-dimensional experiments.

In standard GP regression we use maximum a posteriori (MAP) values for all the model parameters (signal variance, noise variance, length-scales). In the EP methods, when integrating over input-dependent noise variance, we use MAP values for signal variance and length-scales, and when integrating over input-dependent signal and noise variance, we use MAP values for the length-scales. Latent MCMC means that we use EP optimized MAP values for the covariance function parameters and sample only from the latent posterior.

We also ran the experiments by integrating over stationary (not input-dependent) signal and noise variances. However, results with these methods coincide with standard GP regression and the results can be regarded trivial. Thus they are not reported in this paper in order to save space.

The performance of the different methods was assessed by computing the mean log-predictive density
Figure 2: One-dimensional data sets and the EP predictions with uncertainty intervals. Thin black lines correspond to the true signal in the simulated data sets, and the thick gray lines are the GP predictions with EP. The grey area is the 95% credible interval of the prediction. Red lines correspond to the standard GP prediction with MAP values for the signal and noise variance (credible intervals only shown for SP500).

Table 1: The table shows MLPD values for different methods, where higher values correspond to better predictions. For the concrete data ISO means that we have an isotropic covariance functions for all the latent variables, and ARD denotes automatic relevance determination for $f$ and $\tilde{f}$, and an isotropic covariance function for the rest of the latent variables.

| Method      | Simulated 1 | Simulated 2 | Motorcycle | Concrete (ISO) | Concrete (ARD) | SP500 |
|-------------|-------------|-------------|------------|----------------|----------------|-------|

(MLPD) for $N$ test data points

$$\text{MLPD} = \frac{1}{N} \sum_{i=1}^{N} \log p(y^*_i \mid x^*_i, X, y)p(y^*_i \mid x^*_i) \, dy_i^*, \quad (29)$$

where $p(y^*_i \mid x^*_i, X, y)$ is the posterior predictive density for $y^*_i$ and $p(y^*_i \mid x^*_i)$ is the true distribution of $y^*_i$. For the three empirical datasets, we computed the approximate MLPD of the $n$ training data points with 10-fold cross-validation:

$$\text{MLPD} \approx \frac{1}{n} \sum_{i=1}^{n} \log p(y_i \mid x_i, X_{-i}, y_{-i}), \quad (30)$$

where $p(y_i \mid x_i, X_{-i}, y_{-i})$ is the cross-validated posterior predictive density for $y_i$. Higher MLPD values correspond to better predictions.

MLPD values from the experiments are shown in Table 1. We can conclude from the results that integrating over the input-dependent noise variance increases predictive capability greatly in our experiments compared to standard GP regression. Furthermore, integrating over the input-dependent signal variance tends to enchance the predictions even more. In some cases integration over the signal variance is not needed prediction wise, but our results show that even in these cases, it does not harm the predictive quality. The results show that our EP implementation is comparable to the MCMC methods.

The predictive distribution with the SP500 data in Figure 2d illustrates the practical benefits of the input-dependent noise: The period of steady growth between samples 40-80 has clearly lower signal variance compared to the more volatile periods related to financial crisis of 2008 (samples 90-110) and the subsequent shaky growth characterized by debt crises and monetary interventions (samples 110-140).

With our implementation, MCMC was roughly two orders of magnitude slower than EP. This depends highly on the implementation and number of MCMC draws required for convergence. For example, with the SP500 and Concrete data with ARD lengthscales for $\tilde{f}$, the state-of-the-art MCMC methods based on elliptical slice sampling had convergence issues even after thousands of samples, as the results indicate.

5 Discussion

In this work we have introduced a straightforward but an easily implementable and computationally efficient way to integrate over the uncertainty of the noise and signal variance in Gaussian process regression. Our implementation is easy to apply also for input-dependent noise and signal variance, and it further extends the well-known nonstationary GP models. We have tested our EP implementation on several different data sets and showed that the EP results are on par with state-of-the-art MCMC methods. Furthermore, our results show EP can be used in complex problems where even the state-of-the-art MCMC methods have convergence problems.

The scope of this paper was not to compare GPs to other models, but to investigate how integration over signal and noise variance works in the GP framework. Thus, we have ommitted comparisons to other models in this work.

The results indicate that there exists phenomena, where it is advantageous to have input dependent signal variance in addition to the input dependent noise variance. While adding the input-dependent noise variance greatly enhances the predictive quality, we are still left with oscillation of the estimated mean. Using the input-dependent signal variance in addition to the noise makes the estimates smoother and further enhances the predictions.
