Designing and Developing of Savonius Wind Turbine for Efficiency Improvement in Low-Speed Wind Sources

Nantasak Sukurkdee, Punyawee Bumroongrads, Peerapol Sangsawat, and Chawannat Jaroenkhasemmeesuk

Abstract—Wind energy is one of the highest efficiency in renewable energy. Unfortunately, wind energy was not developed much in Thailand because the average wind speed of the city area is limited to the medium-low range which makes wind energy unsuitable for power generation. Recently, there are the researches tried to apply the wind turbine to wind source besides the bus. According to a large amount of vehicles transport from upcountry into the city in Thailand, wind energy can be considered as the potential energy only if the turbine can operate the high efficiency. With this reason, the object of this project focuses on the efficiency factors of a wind turbine to be able to use in low-speed wind energy especially wind that source by the passenger car includes designing and developing wind turbine for propeller’s efficiency increasing. This project used 200-Watt Savonius wind turbine to experiment with the effect of 1) weight of propeller, 2) material of propeller, and 3) swept area of the propeller to the efficiency of the wind turbine. The research and experiment yield the results that all factors are affecting to RPM, electric power and efficiency of Savonius wind turbine. This project can increase the efficiency of small wind turbine about 26% for use in low-speed wind sources.

Index Terms—Renewable energy, wind turbine, efficiency, low-speed wind.

I. INTRODUCTION

The demand for electricity in Thailand is currently higher than the production every year. Fossil fuel is one of the most important fuel to generate electricity, but it causes the major problem of global warming by the emission of greenhouse gas, dust, etc. Moreover, imported fossil fuel may insufficient and leads to independence. With this reason, renewable and alternative energy is researched to promote sustainability such as hydropower, solar energy, etc. The growing trend of renewable energy is higher every year and it should be operated the same percentage as fossil fuel in 2040 [1]. Unfortunately, one of the highest efficiency technologies to generate electricity, wind power, is not interesting much in Thailand especially in the city area. Average wind speed of the city area in Thailand is the medium-low range that is lower than 4-5 m/s as shown in Fig.1. The fastest wind speed is on the island in the Gulf of Thailand about 5.5 m/s [2]. The problem of using a wind turbine to generate electricity is the speed of the wind that makes wind turbine in Thailand isn’t famous because the wind speed was considered too low.

There are two main types of wind turbines, horizontal and vertical axis. All types of wind turbines have varying designs, and different advantages and disadvantages. Advantages of using vertical wind turbine are easy to maintain, easy to rotate with low wind speed, not directional and lower construction and transportation costs. A vertical axis wind turbine is better than horizontal axis wind speed when it uses with the low-speed wind [3]. The wind turbine was researched and adapted to use in various situations such as using with rotatable gear or another source to increase the efficiency of the wind turbine. An energy harvesting such as wind turbines on the highway was researched and found that the efficiency of 34.6 percent was obtained [4].

In 2018, Bangkok is the 8th place of the capital city that has the worst traffic. According to the vehicles data in Thailand, it has a lot of vehicles driving across the city which may be a good opportunity to use the wind beside the vehicle as optional sources.

The global trend of clean energy is the motivation of this project by using a Savonius wind turbine to generate electricity from the wind beside the vehicles. The main objective is designing and improvement a Savonius wind turbine to use with a low wind speed of the vehicle for propeller’s efficiency increasing. The factors of designing and improvement include the weight of propeller, the material of propeller, swept area of the propeller [5]. The control parameters of this wind turbine are twin blade, rotating in clockwise, 200 watts of a generator and using low wind speed as the source.

The average speed of the vehicle crossing the city to Bangkok is 50–80 km/hr. This speed was collected from the
standard vehicle in Thailand include a sedan, hatchback, minivan, and crossover. Wind speed beside the car was simulated from Autodesk Flow Design in Fig. 2 to analyze the form and velocity of wind beside a car to set the wind sources in the experiment. The wind is increasing when the car passed, then the fastest speed is between 55 and 85 cm of car height from the ground.

![Fig. 2. The wind profile in front of a car model at 6.84 km/hr (a) Front view (b) Side view.](image)

The efficiency of a wind turbine ($C_p$) as shown in (1) is the comparison between wind turbine power ($P_w$) and wind power ($P_a$). Equation of wind turbine efficiency can be solved by Eq. (1), where $V$ is voltage, $I$ is electric current (Amp), $\eta_g$ is generator efficiency, $\eta_c$ is controller efficiency, $\rho$ is air density (kg/m$^3$), $A$ is the swept area (m$^2$), $V$ is wind speed (m/s) [5], [6].

$$C_p = \frac{P_w}{\frac{1}{2}\times \eta_g \times \eta_c \times \rho \times A \times V^3}$$  \hspace{1cm} (1)

A Savonius wind turbine is one of the famous types of vertical axis wind turbine that is good to use in Thailand because it is high efficiency with low speed. Savonius wind turbines are a type of vertical axis wind turbine, used for converting the force of the wind into torque on a rotating shaft. Specification of the Savonius wind turbine is a curve of propeller that is impacted by the wind. The ideal efficiency of the Savonius wind turbine is 0.2.

### II. METHODOLOGY

#### A. The Wind Profiles and Wind Source Setting Up

The testing of the low wind speed at each position is the way let us know the profile of wind speed. Testing uses an anemometer to test the speed at 10-100 cm. from the ground and 1.5 m. from the center of the source. After that the wind profile was predicted by using linear regression analysis as shown in Fig. 4.

![Fig. 4. Wind source profiles (m/s) at various height and offset.](image)

The profiles of wind sources were analyzed using the speed and amount of wind to design the height area to increase the swept area as shown in Table I. Table I shows the percent of average speed from wind source which was divided into various height range. Case 4 shows the most effective range to analyze and design to expand the area of a wind turbine in 40-60 height. This work selected the 4th case to be the first improving.

| Height (cm) | Case1 | Case2 | Case3 | Case4 | Case5 | Case6 |
|------------|-------|-------|-------|-------|-------|-------|
| 90         | 7.7   | 18.5  | 7.7   | 31.7  | 7.7   | 7.7   |
| 80         | 10.8  | 23.9  | 10.8  | 37.7  |       |       |
| 70         | 13.1  | 27    | 41.4  | 41.4  |       |       |
| 60         | 13.8  | 28.3  |       |       |       |       |
| 55         | 14.5  | 28.4  | 42.2  | 42.2  |       |       |
| 40         | 14    | 25.7  |       |       |       |       |
| 30         | 11.7  | 21.3  | 35.2  | 35.2  |       |       |
| 20         | 9.5   | 14.4  | 26.1  | 26.1  | 9.5   | 9.5   |
| 10         | 4.9   | 4.8   | 14.4  | 4.9   | 7.4   |       |

#### B. Rotating Test, Electric Power and Retardation Time Test

Rotating, electric power and retardation time test the original Savonius wind turbine to compare with material changing and new design wind turbine [7]. Material is changed to lighter material then, remove the stud of the propeller to reducing weight. Designing the wind turbine by increasing a swept area that is impacted by wind. The designing wind turbine is referred to case 4 of Table I that the fastest average speed is between 65-85 cm. adding the swept about 680 cm$^2$ by using coroplast because it isn’t heavy. The testing is referred to wind profile that is tested at 65 and 80 cm. from ground and 1.5, 3 m from the source.

### III. RESULT AND DISCUSSION

As mention above, the improvement of a wind turbine in
this work includes 1) weight of propeller, 2) material of propeller, and 3) swept area of the propeller. For the weight of propeller, the studs in wind turbine installation set were removed, the weight of installation set decreases to 0.666 kg from 2.154 kg that is about 69% of the original decreasing. The wind turbine after stud removing was analyzed the wind resistance and found that it can resist the wind to 40 m/s. The material of propeller was changed to reduce the weight of propeller which was decreased to 2.274 kg form 2.628 kg (about 13.5% of the original).

The designing wind turbine was increased the swept area by adding coroplast in case 4 area. The swept area was increased to 6,612.2 cm² from 5,932.2 cm². Each step of wind turbine improvement was experimented to investigate rotating, electric power generation and retardation time. The result was shown in Fig. 5-7.

The Fig. 5 shows that the rotation cycle of both graphs has a similar trend, but different in the rotation cycle. Therefore, at the height of the wind source 80 cm, can perform higher rotation cycle than 65 cm. The aluminum alloy blade will have the highest rpm speed at the side of the side equal to 20 cm on the left thread. The acrylic and leaf designs that have been updated will have the highest speed per minute at the side distance of 10 cm on the left thread. The result of an improved wind turbine can increase the rotation by about 33%, which will affect the next experiment, power generations.

The power coefficient of each improved wind turbine has a similar trend as shown in Fig. 6. By showing that the trend of properties is best in the offset at 20 cm, both the origin of the high wind 65 and 80 cm. From the study, it was found that the maximum efficiency of the Savonius wind turbine was 0.2, as shown in Fig. 1. When the maximum value is compared as the percentage of the maximum efficiency at the side-20 cm of the aluminum alloy impeller, acrylic propeller and the propeller designed to improve. It was found that at the height of 65 cm wind source, the highest percentage was 14.93, 16.68, and 30.24, respectively at the height of 80 cm. The highest percentage was 23.6, 36.23 and 52.62 respectively. From the original 26%.

Fig. 7 shows that the weight of struts and propellers effect on the generation of electricity in the absence of wind speed. Due to the wind speed from the side wind at 3 m, which is very low, so there is very little difference between the power generation in this period or almost no effect at all. In the other way at 1.5 m of wind sources, the improved wind turbine can
increase the electric production from 10 W to 50 W.

IV. CONCLUSION

From the testing of the performance of the Savonius wind turbine, the experiment found that the results were satisfactory and achieved the intended purpose and scope. The efficiency of the wind turbine (Cp) using with low-speed wind source can be improved by reducing the weight of wind turbines and increasing the airflow area of the propeller using the wind profile of the car side wind. The calculations show that the energy coefficient has increased significantly with a maximum value of 52.62% compared to the mathematical theory which has seen a higher value from the original 26%. By testing the delay of the time (seconds) that the propeller is still spinning when there is no source of wind to test the power produced during the rotor phase is stopped, it is found that the power has a low power during that period. Thus, it can be concluded that reducing weight does not affect electricity production in improvement and design. According to the improved efficiency, the upgrading wind turbine should be able to be installed and operated on the highway and motorway with 2-digit code in Thailand.
