ABSTRACT

We present a measurement of the mean density profile of Ca ii gas around galaxies out to ~200 kpc, traced by Fraunhofer’s H & K absorption lines. The measurement is based on cross-correlating the positions of about one million foreground galaxies at z ~ 0.1 and the flux decrements induced in the spectra of about 10^6 background quasars from the Sloan Digital Sky Survey. This technique allows us to trace the total amount of Ca ii absorption induced by the circumgalactic medium, including absorbers too weak to be detected in individual spectra. We can statistically measure Ca ii rest equivalent widths down to several mÅ, corresponding to column densities of about 5 \times 10^{10} cm^{-2}. We find that the Ca ii column density distribution follows N_{Ca ii} \sim r_p^{-1.4} and the mean Ca ii mass in the halo within 200 kpc is \sim 5 \times 10^3 M_\odot, averaged over the foreground galaxy sample with median mass \sim 10^{10.3} M_\odot. This is about an order-of-magnitude larger than the Ca ii mass in the interstellar medium of the Milky Way, suggesting that more than 90% of Ca ii in the universe is in the circum- and inter-galactic environments. Our measurements indicate that the amount of Ca ii in halos is larger for galaxies with higher stellar mass and higher star formation rate. For edge-on galaxies we find Ca ii to be more concentrated along the minor axis, i.e., in the polar direction. This suggests that bipolar outflows induced by star formation must have played a significant role in producing Ca ii in galaxy halos.

Key words: galaxies: evolution – galaxies: halos – intergalactic medium – quasars: absorption lines

1. INTRODUCTION

The H & K absorption and emission lines have had an important role in the early developments of spectroscopy and, for about two centuries, have been key to understanding a host of astronomical phenomena ranging from the solar atmosphere to the interstellar medium of distant galaxies.

The labeling convention for the major absorption lines traces its origin back to the work of the German optician and glass manufacturer Joseph Fraunhofer who, in 1814, cataloged over 500 lines in the solar spectrum and designated the principal dark features with letters from A through H (Fraunhofer 1814). He used the letter I to denote the blue end of the visible spectrum and labeled a selected set of weaker lines with lower-case letters. Despite being one of the strongest features in the solar spectrum, the bluer line of the doublet was never labeled by Fraunhofer. His main goal was to measure the refractive indices of various materials and was probably not interested in using pairs of lines closely separated in wavelength. The nineteenth-century literature refers to this second line as H2, H‘, or H ii. According to Pasachoff & Suer (2010), the origin of the modern labeling goes back to John William Draper who in 1843 named the lines as H and k (lower case) in order of decreasing wavelength (Draper 1843). The first person to use the capital K to designate the second H line is Éléuthère Mascart from the Ecole Supérieure de Paris in 1864 (Mascart 1864). The naming convention was straightened out at the first International Astronomical Union meeting, held in Rome in 1922. The Committee accepted that only some of the mostly century-old symbols should be retained. It was decided that only A (O2), a (O2), D (Na), b (Mg), G (Fe & Ca), and H and K were to be preserved and the notation Hz, and Hβ, etc., should be adopted for the hydrogen lines (Hearnshaw 1986).

The H & K lines have played a major role in astrophysics because of their strength and their location in the visible part of the spectrum. They correspond to the fine structure splitting of the singly ionized calcium excited states Ca ii (Ca+) at \lambda = 3934.78 Å (K) and 3969.59 Å (H) in vacuum. Being an abundant refractory element and has ionization potentials of 6.11 and 11.87 eV for Ca i and Ca ii, respectively (Morton 2003), calcium is found in a range of astrophysical environments. Calcium is a refractory element and has ionization potentials of 6.11 and 11.87 eV for Ca i and Ca ii, respectively (Morton 2003). In high-density environments such as the disk of our Galaxy, most of the calcium is found in dust grains. In low-density environments, it tends to be found in Ca iii and other higher-ionization states.

The H & K lines are the only resonance lines in cool-star spectra of the dominant ionization stage of an abundant element that are accessible to ground-based observations. In 1814, Fraunhofer himself detected these absorption lines in the spectra of various stars. About a century later, Hartmann (1904) detected H & K absorption due to interstellar matter, opening a new window on the mapping of the gas distribution in the Galaxy. On extragalactic scales, Ca ii absorption was detected by Boksenberg & Sargent (1978) in the spectrum of the quasar 3C 232. The first detections of the H & K absorption due to galaxy halos followed (Boksenberg & Sargent 1978; Boksenberg et al. 1980; Blades et al. 1981). Figure 1 shows a compilation of the detections reported in the literature (see the Appendix for more detail). In such low-density environments, the mapping of Ca ii has been limited to the immediate vicinity of galaxies, i.e., within about 30 kpc due to the weakness of these absorption lines. Wild & Hewett (2005) and Wild et al. (2007) used samples of Ca ii absorbers from the Sloan Digital Sky Survey (SDSS; York et al. 2000) to estimate the mean dust reddening and star formation rate (SFR) of these systems. The first detection of calcium H & K absorption by a high-velocity cloud (HVC) was reported by West et al. (1985), showing that the Milky Way halo is enriched with metals. In
this paper, we extend the use of the H & K lines to the circum- and inter-galactic context.

We present a measurement of the mean density profile of Ca $\text{ii}$ in galaxy halos out to $\sim 200$ kpc. We are also able to explore its dependence on stellar mass, SFR, and azimuthal angle, and place strong constraints on both the total amount of Ca $\text{ii}$ in galaxy halos and its origins. Our statistical analysis is based on cross-correlating the positions of about one million foreground galaxy halos and its origins. Our statistical analysis is based on the literature. Only those with impact parameter ($r_p$) larger than 3 kpc are included, among which two have impact parameter larger than 30 kpc. Details are presented in the Appendix. (A color version of this figure is available in the online journal.)

Figure 1. Individual Ca $\text{ii}$ absorbers with known associated galaxies from the literature. Only those with impact parameter ($r_p$) larger than 3 kpc are included, among which two have impact parameter larger than 30 kpc. Details are presented in the Appendix.

2. DATA ANALYSIS

Our goal is to statistically measure the H & K absorption lines imprinted in the spectra of distant quasars by the circumgalactic medium (CGM) of low-redshift galaxies and estimate the mean column density of Ca $\text{ii}$ within their virial-radius and beyond. To do so we measure the mean rest equivalent width, $\langle W_{\text{R}}^{\text{K}} \rangle$, of the Ca $\text{ii}$ K line imprinted on quasar spectra as a function of impact parameter (projected galactocentric distance, $r_p$) from low-redshift galaxies. A similar technique has been used at higher redshifts to probe various UV absorption lines by Steidel et al. (2010) with the Keck Baryonic Structure Survey and Bordoloi et al. (2011) using the zCOSMOS survey (Lilly et al. 2007).

When Ca $\text{ii}$ absorption is in the linear regime of the curve of growth, the rest equivalent width is related to Ca $\text{ii}$ column density through

$$N_{\text{Ca} \text{ii}} = 1.13 \times 10^{20} \text{ cm}^{-2} \frac{W_{\text{R}}^{\text{K}}}{f \lambda^2},$$

(1)

where both $W_{\text{R}}^{\text{K}}$ and $\lambda$ are in units of $\text{Å}$ and the oscillator strength $f$ for the Ca $\text{ii}$ K line is 0.648 (Safonova & Safonova 2011). This relation is valid when the optical depth for Ca $\text{ii}$ K absorption is smaller than unity, which corresponds to $N_{\text{Ca} \text{ii}} \lesssim 10^{12.5} \text{ cm}^{-2}$ (assuming the Doppler broadening factor $b \sim 10 \text{ km s}^{-1}$). As shown below, this is the regime of interest in the present study.

Our analysis makes use of data from SDSS DR7 (Abazajian et al. 2009). We use the value-added MPA-JHU catalog (Kauffmann et al. 2003; Brinchmann et al. 2004), which includes stellar mass and SFR measurements for 819 unique galaxies with a mean redshift $z \sim 0.1$. We also supplement the catalog with the position angle and minor-to-major axis ratio ($b/a$), retrieved from SDSS skyserver. To ensure that the induced Ca $\text{ii}$ absorption is not blended with that of our Galaxy, we select galaxies at redshifts $z_{\text{gal}} > 0.02$. We select quasars as background sources (Schneider et al. 2010) and use the improved redshift estimates given by Hewett & Wild (2010). The sample includes 107,194 quasars with redshifts spanning $0.1 < z < 6.5$.

Absorption measurements are based on continuum-normalized fluxes:

$$R(\lambda) = \frac{F(\lambda)}{\hat{F}_{\text{com}}(\lambda)},$$

(2)

For the extraction of weak absorption information from the noise-dominated flux residuals, accurate estimation of the source flux continuum is crucial. We make use of the SDSS quasar continuum estimates $\hat{F}_{\text{com}}(\lambda)$ given by Zhu & Ménard (2013). In a nutshell, this analysis employed the robust dimensionality-reduction technique nonnegative matrix factorization (NNMF; Lee & Seung 1999; Blanton & Roweis 2007) to construct a basis set of nonnegative quasar eigenspectra, and fit each observed quasar spectrum with a nonnegative linear combination of these eigenspectra. Large-scale residuals not accounted for by the NMF basis set were removed with appropriate median filters. For details regarding this continuum estimation method, we refer the reader to Zhu & Ménard (2013). The continuum estimation requires a robust NMF basis, which restricts the quasar sample to those at $z < 4.7$. In total we are able to use 84,533 quasar spectra. Finally, when selecting background quasars, we require $z_{\text{quasar}} > z_{\text{gal}} > 0.1$.

As we are interested in estimating absorption equivalent widths in the rest frame of selected galaxies at various redshifts, we will shift every flux residual $R(\lambda)$ to the rest frame of the absorbing material throughout the paper. To optimally extract information on absorption lines we use a matched-filter technique (e.g., Schneider et al. 1993) to convolve the residuals $R(\lambda)$ with the expected absorption line profile $P(\lambda)$:

$$R_{\text{c}}(\lambda) = 1 - \int \frac{[1 - R(\lambda')]P(\lambda' - \lambda)d\lambda'}{\int P^2(\lambda' - \lambda)d\lambda'},$$

(3)

where both $W_{\text{R}}^{\text{K}}$ and $\lambda$ are in units of $\text{Å}$ and the oscillator strength $f$ for the Ca $\text{ii}$ K line is 0.648 (Safonova & Safonova 2011). This relation is valid when the optical depth for Ca $\text{ii}$ K absorption is smaller than unity, which corresponds to $N_{\text{Ca} \text{ii}} \lesssim 10^{12.5} \text{ cm}^{-2}$ (assuming the Doppler broadening factor $b \sim 10 \text{ km s}^{-1}$). As shown below, this is the regime of interest in the present study.

Finally, when selecting background quasars, we require $z_{\text{quasar}} > z_{\text{gal}} > 0.1$.

As we are interested in estimating absorption equivalent widths in the rest frame of selected galaxies at various redshifts, we will shift every flux residual $R(\lambda)$ to the rest frame of the absorbing material throughout the paper. To optimally extract information on absorption lines we use a matched-filter technique (e.g., Schneider et al. 1993) to convolve the residuals $R(\lambda)$ with the expected absorption line profile $P(\lambda)$:

$$R_{\text{c}}(\lambda) = 1 - \int \frac{[1 - R(\lambda')]P(\lambda' - \lambda)d\lambda'}{\int P^2(\lambda' - \lambda)d\lambda'},$$

(3)
where \( P(\lambda) \) is normalized with
\[
\int P(\lambda) d\lambda = 1.
\]

When focusing on a single absorption line, \( P(\lambda) \) is chosen to be a Gaussian kernel, with a fixed velocity dispersion of 3 pixels (\( \sim 207 \text{ km s}^{-1} \)). We note that the exact value of the velocity dispersion adopted (2, 3, or 4 pixels) has little effect on the results. To extract information from the Ca\( \text{II} \) doublet, \( P(\lambda) \) is a double Gaussian kernel with a 34.8 Å separation and a doublet ratio of 2 and for which \( \lambda \) is the central wavelength of the blue K line. The convolved flux residuals can be used to obtain a non-parametric measurement of the Ca\( \text{II} \) equivalent width. The K-line rest equivalent width is given by
\[
W_{0}^{K} = \frac{2}{3} [1 - R_{c}(\lambda_{K})],
\]
where the factor 2/3 is to convert the total equivalent width of the doublet to that of the K line.

When measuring the mean Ca\( \text{II} \) rest equivalent width induced by a sample of foreground galaxies, we select quasars for which the expected Ca\( \text{II} \) absorption feature does not fall in the Ly\( \alpha \) forest. We also exclude quasars for which the expected Ca\( \text{II} \) absorption overlaps the quasar’s C\( \text{IV} \), C\( \text{III} \), and Mg\( \text{II} \) emission-line regions, although including these systems in the analysis has little effect on our results.

3. RESULTS

3.1. The Average Ca\( \text{II} \) Absorption Radial Profile

Our estimate of the mean Ca\( \text{II} \) absorption is given by the cross-correlation between the position of foreground galaxies denoted by \( \delta_{g}(r) \) and the absorption rest equivalent width expected in the spectra of quasars, as a function of projected separation \( r_{p} \):
\[
\langle W_{0}^{K}(r_{p}) \rangle = \langle \delta_{g} \cdot W_{0}^{K}(r_{p}) \rangle,
\]
where the ensemble average is taken at the position of every galaxy and includes all background quasars in a radial bin centered on \( r_{p} \). Absorption being a multiplicative effect, we use a geometric mean for the ensemble average, which gives us an arithmetic mean of the corresponding optical depth. However, using an arithmetic mean yields similar results, as expected when measuring weak absorption lines. Our estimator is inverse-variance weighted, using the wavelength-dependent noise given by the SDSS pipeline.

In Figure 2 we show intermediate measurements leading to our estimate of \( \langle W_{0}^{K}(r_{p}) \rangle \). The left panel shows, for four radial bins, the stacked galaxy rest-frame and continuum-normalized quasar fluxes \( \langle R(\lambda) \rangle \) between 3800 and 4100 Å (gray lines). The vertical lines show the expected locations of the H & K lines. The blue lines show the convolved residuals \( \langle R_{c}(\lambda) \rangle \). To estimate the uncertainty, we measure the distribution of the convolved residuals \( \langle R_{c}(\lambda) \rangle \) over the wavelength range between 3800 and 4100 Å and estimate its dispersion. This is illustrated in the right panel of the figure, where the vertical lines indicate the corresponding values of \( \langle R_{c}(\lambda_{K}) \rangle \).

We present the radial dependence of Ca\( \text{II} \) absorption around galaxies in Table 1 and Figure 3. The blue solid circles represent the rest equivalent width estimates \( \langle W_{0}^{K}(r_{p}) \rangle \) derived from measurements of the H & K lines \( \langle R_{c}(\lambda_{K}) \rangle \). We also show the estimates based on the residuals of the K line only \( \langle R(\lambda_{K}) \rangle \), with a single Gaussian kernel) with the gray open diamonds. The conversion to column density is shown in the right panel.
stellar mass of the foreground galaxy sample is random noise. Our results show that, on average, Ca gas is present in the halo of galaxies up to scales comparable to their virial-radius. For reference, the vertical dashed line shows the mean 90% light radius of the foreground galaxy sample ($r_{90} \sim 8$ kpc).

The inset of the figure shows, using a linear scale, the measurements on different scales are largely consistent with no overlap between the angular apertures used around different galaxies, the measurements on different scales are largely uncorrelated as different galaxies tend to be at different redshifts. The inset of the figure shows, using a linear scale, the measurements on scales greater than 200 kpc, which are consistent with different galaxies, the measurements on different scales are largely uncorrelated as different galaxies tend to be at different redshifts.

Figure 3. Rest equivalent width of Ca ii as a function of impact parameter. The blue solid circles show the measurements using spectra convolved with the double Gaussian kernel. The gray open diamonds are measurements using the K line only (with a single Gaussian kernel). The solid line shows the best-fit power law to the measurements at $r_p < 200$ kpc, while the dotted line is the extrapolation of the best-fit profile. The inset shows the measurements and the extrapolation of the best-fit profile on large scales, but in linear scale in the y-axis. The vertical dashed line shows the mean 90% light radius of the foreground galaxy sample ($r_{90} \sim 8$ kpc).

(A color version of this figure is available in the online journal.)

Table 1
The Average Ca ii Absorption Radial Profile

| $r_p$ Bin (kpc) | Median $r_p$ (kpc) | $N_{pairs}$ | $\langle W_0^K\rangle$ (Ca ii) (mÅ) |
|-----------------|-------------------|------------|-----------------------------------|
| (3, 10]         | 7                 | 17         | $435 \pm 68$                      |
| (10, 20]        | 15                | 86         | $132 \pm 33$                      |
| (20, 30]        | 26                | 131        | $59 \pm 27$                       |
| (30, 45]        | 39                | 410        | $40 \pm 15$                       |
| (45, 68]        | 58                | 1106       | $19.5 \pm 8.7$                    |
| (68, 101]       | 87                | 2991       | $16.5 \pm 5.7$                    |
| (101, 152]      | 130               | 7456       | $5.2 \pm 3.4$                     |
| (152, 228]      | 194               | 17348      | $5.8 \pm 2.4$                     |

To validate the robustness of our measurements, we perform two null hypothesis tests. (1) Using Equation (6) we measure the rest equivalent widths at different wavelengths. The left panel of Figure 4 shows the significance of the measurements for 12 randomly selected wavelengths between 3800 and 4100 Å (gray diamonds). For comparison, the Ca ii measurements are shown as blue solid circles. (2) We measure the expected Ca ii rest equivalent widths but, instead of using the corresponding background quasars lying within some impact parameter from the galaxies, we use random quasars with similar redshifts. These results are shown in the right panel of the figure. In both cases our test measurements are consistent with no signal and show that the detection of Ca ii absorption at $r_p < 200$ kpc (Table 1 and Figure 3) is robust and not induced by systematic effects.

3.2. Total Mass of Ca ii in the Halo

We parameterize the radial dependence of the mean Ca ii absorption around galaxies with a power-law functional form

$$\langle W^K_0 (r_p) \rangle = A \left( \frac{r_p}{100 \text{kpc}} \right)^\alpha,$$

where $r_p$ is taken as the median impact parameter in each bin. Performing a least-squares fit to the measurements at $r_p < 200$ kpc, we obtain

$$A = 11 \pm 2 \text{mÅ}$$

and

$$\alpha = -1.38 \pm 0.11.$$

We show the best-fit power law with the blue line in Figure 3, where we also show its extrapolation to larger scales. The expected signal from the extrapolation is below the noise level. The slope shows that the mean Ca ii distribution is steeper than an isothermal profile. Converting $\langle W^K_0 \rangle$ to mean column density ($N_{\text{Ca ii}}$) using Equation (1) and integrating the best-fit profile between 10 and 200 kpc, we estimate the average total Ca ii mass in the halo to be

$$\langle M_{\text{halo}} \rangle = m_{\text{Ca}} 2\pi \int_{10 \text{kpc}}^{200 \text{kpc}} N_{\text{Ca ii}}(r_p) r_p dr_p$$

$$= (5.0 \pm 1.0) \times 10^7 M_\odot,$$

where $m_{\text{Ca}}$ is the atomic mass of calcium.

---

8 We note that this cylindrical mass is obtained using the projected column density. For spherical mass we need to deproject it through inverse Abel’s integral with uncertain assumptions of gas distribution on large scales. The correction factor is $\sim 0.6$ and the average spherical mass is $\sim 3 \times 10^7 M_\odot$, assuming that the power-law distribution extends to infinity. Throughout the paper we will stick to the observable cylindrical mass.
It is interesting to compare the total Ca\textsc{ii} mass in the halo with the total Ca\textsc{ii} mass in galaxies themselves such as the Milky Way. To estimate the total Ca\textsc{ii} mass in the Milky Way disk, we use the average neutral hydrogen H\textsc{i} surface density 10\,M\odot\,pc\(^{-2}\) (∼10\(^{21}\) cm\(^{-2}\), e.g., Kalberla & Kerp 2009), and the typical Ca\textsc{ii}-to-H\textsc{i} ratio \(N_{\text{Ca}\textsc{ii}}/N_{\text{H}\textsc{i}} \sim 10^{-8.9}\) in the interstellar medium (e.g., Gudennavar et al. 2012). Integrating the surface density out to 15 kpc, we obtain \(M_{\text{Ca}\textsc{ii}}^{\text{MW Disk}} \sim 3 \times 10^2\,M\odot\), an order-of-magnitude smaller than the average total Ca\textsc{ii} mass in the halo, suggesting more than 90% of Ca\textsc{ii} in the universe is distributed in circum- and inter-galactic environments. This dramatic difference, however, is likely caused by the difference in the dust depletion levels rather than in the total amount of calcium in different environments. From observations of the Milky Way halo, the gas density in the CGM is more than an order-of-magnitude lower than in the interstellar environment, and therefore there is relatively less calcium depleted onto dust grains (e.g., Wakker & Mathis 2000), resulting in a Ca\textsc{ii} abundance an order-of-magnitude higher. Finally, we note that the total Ca\textsc{ii} mass in the halo above is obtained by averaging over all the foreground galaxies (in the galaxy–quasar pairs), whose median mass is \(\sim 10^{10.3}\,M\odot\).

### 3.3 \textit{H}\textsc{i} Mass Traced by Ca\textsc{ii}

We now attempt to estimate the total amount of H\textsc{i} gas traced by Ca\textsc{ii}. It is known that in cool, dense clouds most of the Ca is depleted onto grains and Ca\textsc{ii} can be the dominant ionization state, while in warm, lower-density medium, Ca is less depleted but the dominant ionization state is usually Ca\textsc{iii} (e.g., Routly & Spitzer 1952; Welty et al. 1996; Wakker & Mathis 2000; Ben Bekhti et al. 2012). Here we make the assumption that the Ca\textsc{ii}-to-H\textsc{i} ratio is steady across the halo and therefore there is relatively less calcium depleted onto dust grains (e.g., Wakker & Mathis 2000), resulting in a Ca\textsc{ii} abundance an order-of-magnitude higher. Finally, we note that the total Ca\textsc{ii} mass in the halo above is obtained by averaging over all the foreground galaxies (in the galaxy–quasar pairs), whose median mass is \(\sim 10^{10.0}\,M\odot\).

Figure 4. Null hypothesis tests showing the robustness of the Ca\textsc{ii} detection. Left panel: significance of rest equivalent width measurements at randomly selected wavelengths. Right panel: significance of rest equivalent width measurements but using random quasars at similar redshifts as those in galaxy–quasar pairs. The blue solid circles show the significance of the Ca\textsc{ii} absorption measurements.

(A color version of this figure is available in the online journal.)

Figure 5. Stellar-mass–SFR diagram of foreground galaxies in galaxy–quasar pairs. The green line separates star-forming and quiescent galaxies. The blue vertical line (\(M_\ast = 10^{10.1}\,M\odot\)) then divides star-forming galaxies into high-mass and low-mass star-forming subsamples, and the red vertical line (\(M_\ast = 10^{10.7}\,M\odot\)) divides quiescent galaxies into high-mass and low-mass quiescent subsamples.

(A color version of this figure is available in the online journal.)

### 3.4 Dependence on Galaxy Properties

We now investigate the relation between galaxy properties (stellar mass \(M_\ast\), SFR, and azimuthal angle \(\phi\)) and the amount of Ca\textsc{ii} in their halos. Considering the bimodal nature of the distribution of galaxies in the stellar mass and SFR space, we divide the sample of foreground galaxies using the following demarcation relation (Moustakas et al. 2013):

\[
\log_{10} \text{SFR} = -0.79 + 0.65 (\log_{10} M_\ast - 10.0),
\]

where SFR is in \(M\odot\,\text{yr}^{-1}\) and stellar mass \(M_\ast\) is in \(M\odot\). This demarcation relation is shown as the green line in Figure 5 and allows us to separate star-forming galaxies from quiescent ones. To divide each population into high-mass and low-mass subsamples, we adopt a stellar mass separation of \(M_\ast = 10^{10.1}\) and \(10^{10.7}\,M\odot\) for star-forming and quiescent galaxies as shown with the vertical lines in Figure 5. This selection takes into account the fact that star-forming galaxies are on average less massive than quiescent galaxies (e.g., Bell et al. 2003; Moustakas et al. 2013). We now explore how the amount of Ca\textsc{ii} in the halo depends on the following parameters.
Stellar mass. We select two samples of galaxies using the mass cuts defined above, combining star-forming and quiescent galaxies. Our measurements show that more massive galaxies have more Ca II in their halos. Although the profiles for different subsamples do not necessarily have the same shape, the reduction in S/N prevents us from placing robust constraints simultaneously on both the amplitude and the slope of the measurements. To evaluate the difference quantitatively, we therefore fit the Ca II density profile with a power-law function with a fixed slope of $\alpha = -1.38$ as found in Equation (8). The best-fit amplitudes are

$$A_{\text{high-mass}} = 15 \pm 2 \text{ mÅ}$$
$$A_{\text{low-mass}} = 7 \pm 2 \text{ mÅ}. \quad (11)$$

For reference, the median stellar masses of high-mass and low-mass populations are $10^{10.5}$ and $10^{9.8} M_\odot$. Thus, within a fixed impact parameter, the dependence of the amount of Ca II on stellar mass is shallower than linear.

Since the halo of higher-mass galaxies is more extended than that of lower-mass ones, we also look at the dependence on stellar mass by measuring the absorption as a function of impact parameter in unit of virial-radius, $r_p/r_{\text{vir}}$. To estimate the virial-radius-scaled profiles are shown in the right panel of Figure 5 (Equation (10)). We divide the galaxy sample into high-mass and low-mass sub-samples at $M_\ast = 10^{10.5} M_\odot$, as shown by galaxy–galaxy lensing studies (e.g., Mandelbaum et al. 2006). The virial-radius is then estimated to be

$$r_{\text{vir}} = \frac{200 \text{ kpc}}{M_{\ast} / (10^{10.3} M_\odot)^{1/5}}. \quad (14)$$

The virial-radius-scaled profiles are shown in the right panel of Figure 6. Fitting the dependences with a power law, keeping the slope $\alpha$, we find that the best-fit amplitudes (at $r = 0.5 r_{\text{vir}}$) are

$$A'_{\text{high-mass}} = 10 \pm 2 \text{ mÅ}$$
$$A'_{\text{low-mass}} = 9 \pm 2 \text{ mÅ}, \quad (15)$$

consistent with each other. This shows that the amount of Ca II in the halo is, on average, more closely related to the dark matter mass than the stellar mass. In other words, the results indicate that the total Ca II mass within virial-radius follows roughly

$$M_{\text{halo}} \sim M_{\text{vir}} \sim M_\ast^{1.5}. \quad (16)$$

Star formation rate. We now divide the galaxy sample into star-forming and quiescent galaxies using the demarcation represented by the green line in Figure 5 (Equation (10)). We show the corresponding column density profiles of Ca II in the left panel of Figure 7. Our measurements show that, on average, star-forming galaxies are surrounded by more Ca II than quiescent systems. We fit the Ca II density profile with a power-law function fixing the slope $\alpha$ and find the amplitudes to be

$$A_{\text{star-forming}} = 12 \pm 2 \text{ mÅ}$$
$$A_{\text{quiescent}} = 6 \pm 2 \text{ mÅ}. \quad (17)$$

In the right panel, we show the column density profiles normalized by the estimated virial-radius of the galaxies. This removes the stellar mass dependence and the SFR dependence is slightly stronger with best-fit amplitudes:

$$A'_{\text{star-forming}} = 13 \pm 2 \text{ mÅ}$$
$$A'_{\text{quiescent}} = 5 \pm 2 \text{ mÅ}. \quad (18)$$

This result indicates that either star formation (or a physical process correlated with it) is responsible for an excess of Ca II in galaxy halos or that Ca II is suppressed in the halo of quiescent.
Zhu & Ménard

Figure 7. Same as Figure 6, but for SFR dependence. There is more Ca\textsc{ii} around star-forming galaxies than quiescent ones. The dependence is stronger after normalizing impact parameter with virial-radius thus removing the stellar mass dependence.

(A color version of this figure is available in the online journal.)

Figure 8. Dependence of the total amount of Ca\textsc{ii} in the halo on stellar mass and SFR. The total amount of Ca\textsc{ii} is estimated by fitting the measured absorption radial profile with a power-law form with a fixed slope of $\alpha = -1.38$ and integrating the best-fit profile between $0.05 r_{\text{vir}}$ and $r_{\text{vir}}$ (10 kpc and 200 kpc for a $10^{10.3} M_\odot$ galaxy).

(A color version of this figure is available in the online journal.)

Table 2
Average Ca\textsc{ii} Mass in the Halo

| Sample                  | Median $M_*$ ($10^{10} M_\odot$) | Median $r_{\text{vir}}$ (kpc) | $\langle M_{\text{Halo}}(\text{Ca} \textsc{ii}) \rangle$ ($10^4 M_\odot$) |
|-------------------------|----------------------------------|-------------------------------|--------------------------------------------------------------------------------|
| High-mass star-forming  | 3.3                              | 221                           | 9.5 ± 1.8                                                                      |
| Low-mass star-forming   | 0.4                              | 143                           | 4.1 ± 1.8                                                                      |
| High-mass quiescent     | 9.5                              | 274                           | 3.8 ± 1.8                                                                      |
| Low-mass quiescent      | 2.2                              | 205                           | 1.4 ± 1.8                                                                      |
| All                     | 2.0                              | 200                           | 5.0 ± 1.0                                                                      |

Note. $^a$ Average total Ca\textsc{ii} mass in the halo between 0.05 $r_{\text{vir}}$ and 1 $r_{\text{vir}}$ (between 10 kpc and 200 kpc for a $10^{10.3} M_\odot$ galaxy).

galaxies. We note that no significant difference is detected on large scales. It is possible that the SFR dependence is only significant on small scales.

In Figure 8 and Table 2, we summarize the total Ca\textsc{ii} mass in the halo (measured between 0.05 $r_{\text{vir}}$ and $r_{\text{vir}}$ using Equation (9)) for the four galaxy subsamples. In short, we find that there is more Ca\textsc{ii} in the halo of galaxies with higher stellar mass and higher SFR.

Azimuthal angle. We now constrain the spatial distribution of Ca\textsc{ii} as a function of the location of the gas with respect to the disk of the galaxy. To do so we select edge-on galaxies with minor-to-major axis ratio $b/a < 0.55$, and for a given galaxy–quasar pair we measure the azimuthal angle $\phi$ of the quasar from the galaxy’s minor axis (determined from the position angle). We then divide the galaxy–quasar pairs into two subsamples: $|\phi| < 45^\circ$ (along the minor axis) and $|\phi| > 45^\circ$ (along the major axis) and measure the average Ca\textsc{ii} absorption for each subsample. Figure 9 shows the measured Ca\textsc{ii} absorption radial profiles. We find that, on average, the absorption is stronger along the minor axis (in the polar direction) than along the major axis (parallel to the disk plane). Fixing the slope $\alpha$, we find that the best-fit amplitudes are

$$A_{\text{polar}} = 18 \pm 3 \text{ mÅ}$$
$$A_{\text{disk}} = 6 \pm 3 \text{ mÅ}.$$ (19)

This indicates that there is more Ca\textsc{ii} perpendicular to the disk and that bipolar outflows driven by star formation (or a process correlated with it) may be one of the major sources for Ca\textsc{ii}. We note that no significant excess is detected on large scales. It is likely that the azimuthal angle dependence itself depends on the galactocentric distance. Bordoloi et al. (2011) reported a similar effect by measuring Mg\textsc{ii} absorption around galaxies and was able to detect an azimuthal dependence only within $\sim 50$ kpc from the galaxies.
4. SUMMARY AND DISCUSSION

The Ca II H & K absorption lines have been used for two centuries to study a host of astrophysical phenomena. In this paper, we have extended the use of these lines to the circum- and inter-galactic contexts by measuring the galaxy–Ca II gas spatial correlation function. Using spectra of about 10^5 quasars from the SDSS DR7 data set, we have measured the mean Ca II absorption around one million low-redshift galaxies with median M_* ≈ 10^{10.3} M_☉ on scales ranging from about 10 to 200 kpc. This statistical technique allows us to probe absorption lines down to rest equivalent widths of many millangerstroms and to be sensitive to the total amount of Ca II around galaxies.

The detection of absorption features relies on the ability to accurately estimate the intrinsic spectral energy distribution of the background source. To do so we have used the continuum estimation method presented in Zhu & Ménard (2013), based on a vector decomposition technique. The analysis presented in this paper is based on the cross-correlation between galaxy positions and the flux decompositions in the background quasar spectra. It has allowed us to obtain the following results.

1. We detect Ca II H & K absorption out to projected galactocentric distance r_p ∼ 200 kpc (about virial-radius). This is about an order-of-magnitude farther out than previous studies based on individual absorber detections. Our sensitivity allows us to probe Ca II column densities down to about 5 × 10^{10} cm^-2.

2. The mean spatial distribution of Ca II gas around galaxies follows a power-law column density profile with a slope α = −1.38 ± 0.11, at r_p < 200 kpc (see Equation (7)), which is steeper than an isothermal profile. We estimate the total Ca II mass in the halo within 200 kpc to be ∼ 5 × 10^8 M_☉, averaged over the foreground galaxy population. This is an order-of-magnitude higher than the total Ca II mass in the Milky Way disk, suggesting that more than 90% of Ca II in the universe is in the circum- and inter-galactic environment.

3. The amount of Ca II in the halo is larger for galaxies with higher stellar mass. We find that the mean Ca II absorption at fixed virial-radius-normalized impact parameter is independent of stellar mass. This suggests that the Ca II mass in the halo is more closely related to the dark matter halo mass rather than the total stellar content of galaxies.

4. We find, at fixed stellar mass, more Ca II in the halo of star-forming galaxies than quiescent ones by a factor of a few.

5. For edge-on galaxies we find that Ca II is preferentially distributed along the minor axis (in the polar direction).

These results provide new constraints on the gas distribution around galaxies and bring new elements to our understanding of the cosmic baryon cycle. They also provide quantitative challenges for theoretical models for galaxy formation and evolution.

1. The SFR dependence of the amount of Ca II is similar to that of the highly ionized O VI recently found by the HST COS-halos team (Tumlinson et al. 2011). These results imply that star formation, or a process correlated with star formation, is responsible either for injecting Ca II and O VI into the halo or keeping a large amount of calcium and oxygen in the halo in certain physical condition. The azimuthal angle dependence of Ca II and Mg II absorption (Bordoloi et al. 2011, 2012; Kacprzak et al. 2011; Bouché et al. 2012; K. H. R. Rubin et al., in preparation), which shows that low-ionization gas is more abundant and more kinematically violent in the polar direction of edge-on galaxies, suggests that bipolar outflows driven by star formation must have played a significant role in injecting metals into the halo. This is also in agreement with the ubiquitous outflows found in post-starburst/star-forming galaxy spectra at various redshifts (e.g., Tremonti et al. 2007; Weiner et al. 2009; Rubin et al. 2010, see Steidel et al. 2010 for more evidence and a review). Following a period of star formation, the fate of Ca II ions is unclear.

In contrast to the strong SFR dependence of metal lines, there appears to be no statistically significant difference between the Lyα absorption by neutral hydrogen around star-forming galaxies and that around quiescent ones (Thom et al. 2012), suggesting that neutral hydrogen and metals in the halo could have very different origins or be distributed separately in phase space.

2. The amount of Ca II in the halo is correlated with stellar mass. This dependence is shallower than linear, such that the total Ca II mass is more closely related to dark matter mass than stellar mass. This may have the same cause as the mass–metallicity relation—the metallicity of interstellar gas decreases with stellar mass because metals are more easily expelled from low-mass galaxies due to their shallower gravitational potential. This will result in higher metal (halo)-to-stellar mass ratio for lower-mass galaxies. It is interesting to note that Churchill et al. (2013) had similar results regarding Mg II in the halo, and Tumlinson et al. (2011) found that the total O VI mass in the halo shows even less dependence on stellar mass.

Large and homogeneous surveys of the sky have allowed us to probe the distribution of matter in low-density environments. From the SDSS only, we now have measurements of the galaxy–galaxy correlation function from clustering analyses (e.g., Masjedi et al. 2006; Jiang et al. 2012), the galaxy–mass correlation from gravitational lensing (e.g., Mendelbaum et al. 2006), the galaxy–dust correlation from reddening measurements (Ménard et al. 2010) and, from the work presented in this paper, the galaxy–gas correlation function obtained by measuring statistical absorption by metals. These new observational probes are providing us with a more complete description of the matter distribution around galaxies.

This analysis shows the potential of using the ever-growing data from large surveys for absorption line studies. The automatic continuum estimation method presented in Zhu & Ménard (2013) and the cross-correlation technique presented in this paper are generic and readily applicable to any large data set from ongoing and future surveys such as BOSS (Schlegel et al. 2009), eBOSS (Comparat et al. 2013), BigBOSS (Schlegel et al. 2011), and PFS (Ellis et al. 2012).
