Published online 2020 December 19.

Abstract

Background: As the pandemic of coronavirus disease 2019 (COVID-19) in Wuhan raised public health concerns, many studies were conducted to reveal the risk factors of the disease and predictive prognostic indicators to plan the treatment strategies and commence therapies earlier. Although specific parameters, including age, gender, chronic diseases, D-dimer, and neutrophil-lymphocyte-ratio play a curial role in COVID-19, the association between mortality and the extent of lung involvement in the initial computerized tomography (CT) scan of patients diagnosed with COVID-19 has not been well documented in the literature.

Objectives: We compared two groups (CT-1 and CT-2) in terms of lung involvement in the initial CT of patients admitted to the emergency unit and then hospitalized with COVID-19.

Methods: Using the digital data system of Izmir Bozyaka Training and Research Hospital, Turkey, subjects diagnosed with COVID-19 in April 2020 were retrospectively screened. For each of the 90 patients, the initial CT scans on admission were evaluated for the extent of lung involvement and classified as CT-1 (≤ 5% of lung involvement, n: 45) and CT-2 (> 5% of lung involvement, n: 45).

Results: There was not any statistical significance between two different CT groups regarding mortality and length of stay of patients in hospital with COVID-19 (P = 0.72 and P = 0.51, respectively). Neutrophil counts were found to be statistically significant and higher in CT-2 group than the CT-1 (P = 0.02) group. The length of stay in hospital was correlated with age, neutrophil-lymphocyte ratio (NLR), neutrophils, lymphocyte, and only the correlation between length of stay in hospital and age was significant (P = 0.01).

Conclusions: The size of involvement is not a predictive indicator for mortality and length of stay in hospital in patients with COVID-19.

Keywords: COVID-19, Neutrophils, Tomography, X-Ray Computed Tomography

1. Background

A novel coronavirus with a characteristic crown morphology at scanning electron microscopy, causing coronavirus disease 2019 (COVID-19) that is spread by human-to-human transmission due to close contacts, was identified in China and announced by the World Health Organization (WHO) as a pandemic on Mar 11, 2020 (1). No specific antiviral drugs are available to treat COVID-19; thus, early detection and adherence to medical isolation are crucial (2). To date, computerized tomography (CT) images are used by physicians for a fast and effective diagnosis of COVID-19 (3). Based on the literature, patchy ground-glass opacities with interlobular septal and vascular thickening, consolidative opacities with a rounded pattern, and a peripheral distribution are the basic findings of COVID-19 in chest CT (4). These findings are helpful to the radiologist in the early detection and diagnosis of patients. Early disease recognition can speed up treatments and prompt rapid patient isolation (5). Chest CT cannot alone fully exclude the diagnosis of COVID-19, particularly in the early stage of the infection (3, 4). Because of the prodromal phase of COVID-19, viral infection manifests with symptoms before the emergence of imaging manifestations (6). A normal chest CT scan does not exclude the diagnosis, and also CT findings can vary as pneumonia progresses (4, 5). The data of CT findings for COVID-19 in the literature indicate similar features to the other coronaviruses (severe acute respiratory syndrome (SARS) and the Middle East respiratory syndrome (MERS)) (7). The diagnosis of COVID-19 with CT scan is more sensitive than the initial reverse transcription-polymerase chain reaction (RT-PCR) and is also relatively simple and quick (8). Because of its invasiveness and objectivity, CT scan is also used to follow up patients with COVID-19. Although the chest CT examination plays a crucial role in the initial diagnosis of COVID-19, the relationship between the initial CT findings, including the extent of the involvement, and mortality and length of stay in hospital has not well been documented yet.

The neutrophil-lymphocyte ratio (NLR) was known as...
Belice T et al.

an indicator of inflammatory status, and a higher level of
NLR in a patient with COVID-19 has been proved as a risk
factor of mortality (9, 10). The negative outcomes of COVID-19
were found to be associated with a higher NLR, mostly an
NLR of > 3.13 (11). Thus, the higher NLR levels were known
as an indicator of the severity of COVID-19 as well as a hy-
perinflammatory state (11). However, the counts of neu-
trophil, NLR, and lymphocyte have not been studied in de-
tail to compare the extent of lung involvement in CT. Fur-
thermore, the association of mortality with the extent of
lung involvement in the initial CTs of patients diagnosed
with COVID-19 has not well been documented in the litera-
ture.

2. Objectives

Finding the answer to the question of whether the size
of infected areas in the lung is associated with mortality
and length of stay in hospital in patients with COVID-19 is
essential. The present study aimed at revealing whether
the extent of COVID-19 lung involvement in CT could pre-
dict the disease aggravation and assessing the association
between the extent of lung involvement and the mortality
and length of stay in hospital.

3. Methods

3.1. Data Collection and Study Design

Patients diagnosed with COVID-19 were retrospectively
screened using the digital data system of Izmir Bozyaka
Training and Research Hospital, Turkey. Inclusion criteria
were the age of 18 years or more and hospital admission
with COVID-19 from April 1, 2020, to April 30, 2020. G-Power
(ver. 3.1.9.4) software was used to estimate the sample size
considering a type 1 of 5% error and test power of 85%. Us-
ning random sampling, the participants were selected from
the hospital data system in April 2020. The exclusion crite-
rion was the subjects who did not meet the inclusion cri-
teria. Radiologists reported all initial CT images as the per-
centage of lung involvement during admission in the pan-
demic office of the emergency unit. The time interval from
disease to CT was the same for all the cases, and it was re-
ported during the admission phase. For each of the 90 pa-
tients, the initial CT scans on admission were evaluated for
the percentage of lung involvement, and then we classified
the patients as CT-1 (≤ 5% of lung involvement, n = 45) and
CT-2 (over 5% of lung involvement, n = 45).

3.2. Statistical Analysis

An independent t-test and one-way analysis of vari-
ce (ANOVA) were employed to compare the variables.
The results were presented using descriptive statistics; mean ± standard deviation (SD) for continuous variables,
and the number and percentage for categorical variables.
For numeric variables, first, the normal distribution of
the data was tested using the one-sample Kolmogorov-
Smirnov test, and according to the results of this test, the
results of numeric variables were described using mean ±
SD, minimum, and maximum. For the statistical analysis,
the Statistical Package for the Social Sciences (SPSS) soft-
ware (IBM SPSS for Windows, ver.24) was used. P-values of
< 0.05 were considered statistically significant.

4. Results

4.1. Patients

A total of 90 patients with 49 (54.4%) men (M = 60.9
years, SD = 16.1) and 41 (45.6%) women (M = 66.9, SD = 17.8)
were included in the present study. The mean age was 66.76
years (SD = 19.10) in the CT-1 group and 61.67 years (SD =
14.97) in the CT-2 group. The mean age between the two
groups was not statistically significant (P = 0.16). When
the patients were compared in terms of gender, no statis-
tical significance was found between length of stay in hos-
pital, mortality, and lung involvement in CT between men
and women (P = 0.14, P = 0.78, and P = 0.67, respectively).
When mortality rates were compared with the parameters,
including neutrophils, NLR, lymphocyte using an indepen-
dent t-test, a statistically significant difference was found
between mortality rates and parameters, including neu-
trophils and NLR (P = 0.06 and P = 0.02, respectively). In
other words, as NLR and neutrophil values increased, mor-
tality rates increased. The length of stay in hospital was cor-
related with age, NLR, neutrophils, and lymphocyte, but
only the age was positively correlated with length of stay
in hospital (P = 0.00).

4.2. The Extent of Lung Involvement and the Length of Stay in
Hospital

The length of stay in hospital was 8.24 days (SD = 1.083)
in the CT-1 group and 7.34 days (SD = 0.832) in the CT-2
group. The mean length of stay between the two groups
was not statistically significant (P = 0.51).

4.3. The Extent of Lung Involvement and Mortality

The total number of fatal cases was 9 (% 10), includ-
ing six men (12.2%) and three women (7.3%). CT-1 and CT-2
groups were compared with the Chi-square test for mortal-
ity, and the percentage of fatal cases was 8.9% (n = 4) in the
CT-1 group and 11.1% (n = 5) in the CT-2 group. However, no
statistically significant difference was found between the
extent of lung involvement and mortality (P = 0.72).
4.4. Comparison the Counts of the Neutrophil and Lymphocytes, and NLR with the Extent of Lung Involvement

The following results were found in the CT-1 group: NLR: 5.7 (SD = 9.82), neutrophil: 5.06 × 10^3/µL (SD = 3.13), and lymphocyte: 1.61 × 10^3/µL (SD = 6.61), whereas they were as follows in the CT-2 group: NLR: 6.6 (SD = 8.82), neutrophil: 7.52 × 10^3/µL (SD = 6.49), and lymphocyte: 1.62 × 10^3/µL (SD = 0.83). We compared CT-1 and CT-2 groups for NLR, neutrophil, and lymphocyte. Only neutrophil levels were found with a statistically significant difference between both groups. In other words, neutrophil counts were statistically higher in the CT-2 group (P = 0.02).

5. Discussion

In the early days of the emergence of COVID-19, most of the cases were determined to report exposure to food from the Huanan Seafood Wholesale Market (12). The pathogenesis of COVID-19 is still not wholly understood, and cytokine storm is thought to play crucial roles in disease severity (13). However, around 81% of patients with COVID-19 develop a mild type of disease, and they never need hospitalization (14). The severity of COVID-19 varies from mild to severe, and it cannot be easily predicted using a specific tool or criteria beforehand. However, in several studies, some of the parameters have been shown to be associated with mortality and length of stay in hospital in patients with COVID-19. In a study on 191 patients diagnosed with COVID-19 from China, the most crucial risk factors were age, having higher sequential organ failure assessment (SOFA) scores, and D-dimer of over 1 µg/mL, and these findings could give physicians an idea about poor prognosis at an early stage (15). In 338 patients diagnosed with COVID-19 in New York from March 10 - 26, 2020, a chest x-ray severity score was predictive of risk for hospital admission and intubation (16). Wang et al. revealed that C-reactive protein (CRP) could be a predictive marker in COVID-19, and its threshold value was 26.9 mg/L to anticipate the possibility of aggravation (17). In the present study, we compared two CT groups that were separated based on the extent of lung involvement (less than 5% or over) in patients with COVID-19, and we aimed at revealing whether there was a significant difference in mortality and length of stay in hospital between two groups. There were no statistically significant differences in these parameters from between CT-1 and CT-2 groups (t-test; P = 0.517; Chi-square test, P = 0.725). We could not find another study comparing the extent of lung involvement in the initial CT of patients with COVID-19. Thus, we hope that these findings can be valuable for further studies.

Viruses can trigger NETosis, the process of neutrophil extracellular traps (NETs) generation, and several diseases, including venous thromboembolism, cancer, diabetes, and infections involved in NETosis (18). Virus-induced NETs can generate inflammation in an uncontrolled way (19). The effect of COVID-19 on both venous and arterial thromboembolism has been shown in many studies (15, 20). The relationship between thromboembolism and COVID-19 is a crucial factor regarding fatal cases because NETosis was proved to trigger the development of thromboembolism (21, 22). In the present study, the parameters of NLR, lymphocyte, and neutrophil were compared both in the CT-1 and CT-2 groups, and only a statistically significant difference was found in neutrophil that was higher in the CT-2 group (P = 0.02). Even though the neutrophil count was higher in the CT-2 group, the mortality and length of stay in the hospital showed no significant difference between the two CT groups. However, in all participants, as the age and parameters, including NLR and neutrophil, increased, mortality rates increased significantly (P < 0.05). These findings can be an answer to the question of why the mortality is not related to the extent of lung involvement in initial CT of patients with COVID-19, but the NLR and neutrophil are associated. The most crucial reason for fatal cases might be associated with NETosis, but not the extent of involvement. Therefore, the initial CTs of patients with COVID-19 would not be a predictor of mortality. We need more data to find a rapid tool for the diagnosis and progression of the disease, including machine learning or artificial intelligence other than CT, clinical, or laboratory findings (23).

This study had several limitations. First, the study included only one center with a small sample, and no patient had a follow-up chest CT after admission. Second, only 90 patients diagnosed clinically and radiologically were included; negative results or other viruses were not included in the analyses. Also, we did not consider the final survival outcome, and the exact causes of death were not known.

5.1. Conclusion

Patients diagnosed with COVID-19 need to be evaluated as soon as possible, and the prognosis should be predicted based on specific parameters, including NLR, gender, age, etc. The extent of lung involvement in COVID-19 was not associated with mortality in the present study, but we need to explore the unknown features of COVID-19 with large samples and further studies.
