Extinction training during reconsolidation has been shown to persistently diminish conditioned fear responses across species. We investigated in humans if older fear memories can benefit similarly. Using a Pavlovian fear conditioning paradigm we compared standard extinction and extinction after memory reactivation 1 d or 7 d following acquisition. Participants who underwent extinction during reconsolidation showed no evidence of fear recovery, whereas fear responses returned in participants who underwent standard extinction. We observed this effect in young and old fear memories. Extending the beneficial use of reconsolidation to older fear memories in humans is promising for therapeutic applications.

[Supplemental material is available for this article.]
antagonist (i.e., propranolol) in the LA after reactivation of the CS+ also appears to interfere with reconsolidation (Debiec and LeDoux 2004), whereas enhancing noradrenaline can facilitate it (Debiec et al. 2011). In rodents, propranolol has also been shown to effectively disrupt the reconsolidation of older conditioned fear memories (60 d [Debiec and LeDoux 2004], 2 d [Muravieva and Alberini 2010]). In humans, the use of propranolol to disrupt the reconsolidation of fear memories has yielded inconsistent findings (for review, see Loneragan et al. 2012). The vast majority of studies in humans have administered the drug prior to memory reactivation (e.g., Kindt et al. 2009; Pountja et al. 2012), thus potentially targeting memory retrieval, not reconsolidation (Muravieva and Alberini 2010). The few studies that have targeted the reconsolidation process with propranolol have demonstrated limited effectiveness (Soeter and Kindt 2012), with disruption of potentiated startle as a measure of fear memory expression, but not autonomic (i.e., skin conductance or SCR) or expectancy measures. A study attempting to target the reconsolidation of older fear memories in patients with PTSD administered propranolol or placebo after patients recalled personal traumatic events (Brunet et al. 2008). Patients given propranolol showed decreased autonomic measures of fear (i.e., SCR and heart rate) a week later, relative to the placebo group; however, this study lacked a non-reactivation control to rule out a general dampening effect of propranolol on autonomic arousal.

Given the toxic effects of most drugs used to target reconsolidation in animal models and the limited results in humans using propranolol, perhaps the most feasible approach is a behavioral intervention that modifies the learned association. The behavioral interference of reconsolidation is based on the premise that the purpose of reconsolidation is to allow an opportunity for an older memory to be updated or strengthened with subsequent retrieval. Precisely timing standard extinction training after memory reactivation to coincide with the reconsolidation process has been shown to result in persistent fear reduction in rodents (Monfils et al. 2009) and humans (Schiller et al. 2010), in comparison to standard extinction. In addition, the behavioral interference of reconsolidation results in plasticity-related changes in the LA in rodents (Monfils et al. 2009; Clem and Huganir 2010) and diminished blood oxygenation level dependent responses in the amygdala (Agrém et al. 2012) and the prefrontal cortex (Schiller et al. 2013) in humans, supporting the notion that this behavioral technique can alter the original fear memory.

Although the effectiveness of this technique has not been investigated in older conditioned fear memories in humans, this has been explored in rodents, and appetitive memories have been examined in humans. Clem and Huganir (2010) found that the behavioral interference of reconsolidation of conditioned fear memories resulted in persistent fear reduction and enhanced synaptic plasticity within the LA, but only in 1-d-old memories. If they waited a week before performing the reconsolidation manipulation, the reactivation–extinction group did not differ from the standard extinction group. These results are in contrast to findings by Xue and colleagues (2012) examining appetitive conditioned place preference in rodents, and drug craving in human addicts. They found that a similar reactivation–extinction/exposure procedure designed to alter the reconsolidation of appetitive memories led to a lasting reduction in expression of 2-d-old conditioned place preference memories in rodents, and a craving reduction in addicts whose drug-taking memories are presumably much older. To assess if older conditioned fear memories can be altered by behaviorally targeting reconsolidation in humans, we adapted a paradigm from Schiller et al. (2010), which demonstrated the long-term effectiveness of this manipulation in 1-d-old memories. Eighty healthy participants were included in the final analysis (n = 79 were excluded based on the studies’ exclusion criteria) (see Supplemental Material for exclusion criteria, demographic information, and questionnaires). Participants were randomly assigned to one of the four experimental groups: Reactivation Day 1, No Reactivation Day 1, Reactivation Day 7, and No Reactivation Day 7. The experiment consisted of three sessions (Fig. 1). During the first session (Day 0) all participants underwent fear conditioning using a discrimination paradigm: one colored square (CS+) was paired with an aversive electric shock (UCS) on half of the trials (eight CS+US and eight CS+ trials, 50% reinforcement), whereas a differently colored square (CS–) was never paired with a shock (ten CS–). Every trial consisted of a CS presentation (4 sec) followed by an inter-trial interval (10–12 sec) during which a fixation cross was presented. In CS+US trials a shock was administered 3.8 sec after CS onset and coterminated with the CS.

The second session was conducted either 1 or 7 d after fear acquisition. Half of the participants underwent extinction training after memory reactivation (Reactivation groups) and the other half underwent standard extinction without prior memory reactivation (No Reactivation groups). In order to reactivate the original fear memory both Reactivation groups received a reminder cue (a single CS+ trial) followed by a 10-min break during which a TV show episode (The Simpsons) was presented. Extinction training followed (i.e., the repeated presentation of CS+ and CS– without reinforcement). Both No Reactivation groups watched the same TV show episode prior to extinction, but immediately after the experimental setup without any reminder cue (see Schiller et al. 2010). This design resulted in four groups: The Reactivation Day 1 group returned to the laboratory 24 h after the first session and received a reminder cue prior to extinction training. The No Reactivation Day 1 group also returned after 24 h, but underwent extinction training only. The Reactivation Day 7 group returned after 7 d and received a reminder cue prior to extinction training whereas the No Reactivation Day 7 group returned after 7 d but did not receive a reminder cue. During extinction training all participants received 20 CS– trials. The number of CS+ trials was adjusted to account for the CS+ reminder trial (i.e., No Reactivation groups received 20 CS+ trials whereas Reactivation groups received only 19 CS+ trials).

The third session was conducted 1 d after the second session. The procedure was the same for all participants. To reinstate the fear memory, participants were exposed to four unsignaled shocks. After a 10-min break, during which all participants watched the same TV show episode (The Simpsons), a reextinction period followed (10 CS+ and 10 CS–).

The CR was defined as the mean differential SCR response (i.e., mean CS+ minus mean CS–). Mean CRs were calculated for early (first four trials) and late (last four trials) acquisition and extinction. In order to examine the return of fear after

![Figure 1](https://www.learnmem.org/339/Learning%26Memory/Reconsolidation-update-can-change-old-fear-memory.png)
reinstatement, we assessed the CR to the first trial of reextinction. Additionally, to assess the recovery of fear from extinction to reextinction we calculated a fear recovery index (i.e., late extinction CR minus first reextinction CR).

Fear acquisition was confirmed with a two-way analysis of variance (ANOVA), Group (Reactivation Day 1, No Reactivation Day 1, Reactivation Day 7, and No Reactivation Day 7) × Time (early and late CR). Participants’ CR increased significantly over time ($F_{(3,79)} = 19.21, P < 0.001, \eta = 0.20$); there was no group effect or interaction. A follow-up t-test across all participants showed that the CR differed significantly from zero in both early ($t_{(79)} = 8.3, P < 0.001$) and late ($t_{(79)} = 15.27, P < 0.001$) acquisition. The same approach was used to confirm fear extinction. Participants’ CR decreased significantly over time ($F_{(3,79)} = 60.07, P < 0.001, \eta = 0.44$); there was no group effect or interaction. A follow-up t-test across all participants showed that participants’ CR differed significantly from zero at the beginning of extinction ($t_{(79)} = 8.5, P < 0.001$), but was not significantly different from zero at the end of extinction ($t_{(79)} = 1.76, P = 0.08$). These results are not surprising given our exclusion criteria (see Supplemental Material) and demonstrate that participants successfully acquired and extinguished fear (Fig. 2).

To test for differences in reinstatement between groups, we conducted a one-way ANOVA for the first CR during reextinction. There was a main effect of group ($F_{(3,79)} = 3.99, P < 0.05$). Independent samples t-tests showed that participants who underwent standard extinction training exhibited significantly higher CRs than those who received a reminder cue prior to extinction (No Reactivation Day 1 group vs. Reactivation Day 1 group, $t_{(38)} = 2.36, P < 0.05$; No Reaction Day 7 group vs. Reactivation Day 7 group, $t_{(38)} = 2.18, P < 0.05$). There was no difference between both Reactivation groups ($t_{(79)} = 0.97, P = 0.34$) and between both No Reactivation groups ($t_{(79)} = 0.87, P = 0.39$). Follow-up t-tests showed that the CR in both Reactivation groups was not significantly different from zero (Reaction Day 1 group, $t_{(19)} = 1.19, P = 0.25$; Reaction Day 7 group, $t_{(19)} = -0.25, P = 0.81$). In contrast, in both No Reactivation groups the CR was significantly different from zero (No Reactivation Day 1 group, $t_{(19)} = 4.4, P < 0.01$; No Reactivation Day 7 group, $t_{(19)} = 2.74, P < 0.05$). Similar results were obtained when assessing the fear recovery index (see Supplemental Material).

The present findings suggest that, similar to young memories, older fear memories can also be updated using extinction training after memory reactivation. We showed that the extinction of 1-d-old and 7-d-old fear memories during the reconsolidation window successfully diminished the fear response after fear reinstatement. These results are consistent with rodent studies using pharmacological blockade of reconsolidation to successfully modify older fear memories (Nader et al. 2000; Debiec et al. 2002). They offer support for the notion that memories are susceptible to modification even after initial consolidation is terminated when new, safe information is introduced during reconsolidation. This further underscores the adaptive value of reconsolidation. Interestingly, the present results are incongruent with the findings of Clem and Huganir (2010), who showed that a comparable behavioral intervention in mice did not prevent the return of 7-d-old fear memories. This might suggest some differences in age-related memory processes between species, specifically that the susceptibility of memories to modifications lasts longer in humans vs. rodents. However, notable differences between these studies might also explain the opposing results. First, the strength of the fear memory might differ. We observed robust fear conditioning in our final sample, although we excluded around 50% of our initial study population because the conditioning or extinction effects were not robust (see Supplemental Material for exclusion criteria). Due to ethical constraints, laboratory-generated fear memories in humans are always mild. Second, although the molecular mechanisms of memory aging are similar across species, the time line might be different. A simple comparison based on the different life expectancies in humans (~70 yr) and mice (~2 yr) shows that 7 d in mice roughly equal 70 d in humans (see Quinn 2005).

Suzuki et al. (2004) addressed both of these concerns—strength and age of memory—in a contextual fear conditioning study in mice. The authors showed that reconsolidation of stronger contextual fear memories (i.e., three foot shocks instead of one) could not be blocked with anisomycin. However, if the reactivation was intensified (i.e., longer reexposure to the training context), anisomycin resulted in a diminished fear response. In a similar vein, older contextual fear memories (8 wk) were not susceptible to change by pharmacological manipulation unless prolonged reactivation sessions were conducted (Suzuki et al. 2004). These results suggest that older and stronger fear memories can also be updated under the right circumstances. Therefore, one could speculate that a behavioral intervention in mice after a prolonged memory reactivation period might also render older fear memories labile and lead to a persistently diminished fear response. However, it is necessary to examine this in future research.

It should be noted that the present study was intended to closely mirror the nonhuman animal research that inspired us (Clem and Huganir 2010), and therefore has two limitations. First, we excluded participants who showed no evidence of fear acquisition or extinction from further participation. In studies examining techniques to diminish fear (e.g., extinction and reconsolidation) across species this is a common exclusion criterion. Second, the strength of the noninvasive, autonomic physiological response typically assessed in human fear conditioning (i.e., SCR) can vary with participants’ race (Johnson and Landon 1965), age, sex, as well as the weather and room temperature (Venables and Mitchell 1996). We did not control for these factors in participant selection or data collection. Due to these constraints, we excluded a significantly higher proportion of participants who failed to meet the exclusion criteria than would...
Reconsolidation update can change old fear memory

be typical in research with rodents, but the criteria were the same. Second, we did not acquire UCS expectancy ratings, a cognitive measure on which participants indicate the likelihood of the UCS on each trial and which is used in some human fear conditioning studies. Although the use of this measure may have resulted in a more robust assessment of fear conditioning and the loss of fewer participants, we chose not to use it because assessing explicit cognitive knowledge is obviously not possible in research in rodents and would have limited the generalizability between our paradigm and the findings in rodents. In addition, emphasizing explicit knowledge of the CS–UCS relationship has been shown to alter the nature of fear learning (Olsson and Phelps 2004; Atlas et al., pers. comm.) and the neural substrates mediating this learning (Fumiyama et al. 2001; Coppens et al. 2009). For these reasons, we limited our fear assessment to a noninvasive, autonomic measure.

The present study is an important step in further characterizing the boundaries within which reconsolidation update mechanisms are viable in humans. As research on reconsolidation progresses, it is becoming increasingly clear that several factors are linked to the effectiveness of targeting reconsolidation to prevent fear (Auber et al. 2013). Understanding the boundary conditions (e.g., strength and age of memory) is critical in order to translate these findings to useful clinical interventions. The present results are only an initial step toward understanding the potential temporal limitations of reconsolidation and further studies with fear memories older than 4 wk are necessary to match the temporal characteristics of PTSD and to distinguish if these results can potentially be translated to acute traumatic fear memories or also to older traumatic fear memories (DSM V, American Psychiatric Association 2013). The present results, however, suggest that the behavioral interference with the reconsolidation of fear memories could be a useful technique to modify fear memories regardless of their age.
