(Dated: April 29, 2022)

We show that the entire continuous model of twisted bilayer graphene (TBG) (and not just the two active bands) with particle-hole symmetry is anomalous and hence incompatible with lattice models. Previous works, e.g., [Song et al., Phys. Rev. Lett. 123, 036401 (2019)], [Ahn et al., Phys. Rev. X 9, 021013 (2019)], [Po et al., Phys. Rev. B 99, 195455 (2019)], and others [Kang et al. Phys. Rev. X 8, 031088 (2018), Koshino et al., Phys. Rev. X 8, 031087 (2018), Liu et al., Phys. Rev. B 99, 155415 (2019), Zou et al., Phys. Rev. B 98, 085435 (2018)] found that the two flat bands in TBG possess a fragile topology protected by the C2zT symmetry. [Song et al., Phys. Rev. Lett. 123, 036401 (2019)] also pointed out an approximate particle-hole symmetry (P) in the continuous model of TBG. In this work, we numerically confirm that P is indeed a good approximation for TBG and show that the fragile topology of the two flat bands is enhanced to a P-protected stable topology. This stable topology implies 4l + 2 (l ∈ N) Dirac points between the middle two bands. The P-protected stable topology is robust against arbitrary gap closings between the middle two bands and the other bands. We further show that, remarkably, this P-protected stable topology, as well as the corresponding 4l + 2 Dirac points, cannot be realized in lattice models that preserve both C2zT and P symmetries. In other words, the continuous model of TBG is anomalous and cannot be realized on lattices. Two other topology related topics, with consequences for the interacting TBG problem, i.e., the choice of Chern band basis in the two flat bands and the perfect metal phase of TBG in the so-called second chiral limit, are also discussed.

I. Introduction

TBG at the first magic angle (θ ≈ 1.05°) exhibits a group of two almost exactly flat bands [1]. Due to the interesting interaction insulating and conducting states [2–32], superconductor states [33–51], and single-particle topology [19, 52–65] in the flat bands, TBG represents one of the most versatile physical systems of recent years [1–17, 19–31, 33–63, 65–114]. Refs. [54, 56] showed that the C2zT symmetry of TBG protects a fragile topology [86, 115–119] of the two flat bands, which is characterized by a Z-valued winding number. The fragile topology manifests itself as a topological obstruction for exponentially decaying Wannier functions satisfying C2zT symmetry for the two flat bands. However, the Wannier obstruction can be removed by adding trivial bands into the consideration [86, 115, 116]. For example, Ref. [55] showed explicitly that symmetric Wannier functions can be constructed if certain additional orbitals are coupled to the fragile topological band protected by C2zT. However, the papers arguing for a trivialization of the bands [54, 55] neglected one (approximate) symmetry of the TBG model [1].

The Bistritzer MacDonald (BM) model [1] of TBG has an approximate particle-hole symmetry P first pointed out in Ref. [56]. It was already pointed out in Ref. [56] that with this approximate symmetry, there seems to be a further, stable topology in TBG, but this result was not further expanded. We here numerically confirm that the P symmetry (defined in Section II B) in the BM model of TBG is extremely small (< 0.01). Thus we count P symmetry as a good approximation for the low energy physics in TBG. We prove that if the C2zT protected winding number of the two flat bands is odd (true in TBG), then the two flat bands have a stable topology protected by P, which is characterized by a Zl invariant δ. In contrast to the fragile topological bands, which can be trivialized by being coupled to certain trivial bands, the Z2 topology, as well as the Wannier obstruction implied by the Zl invariant, is stable against adding trivial bands that preserve the P symmetry. We further proved that, in the presence of C2zT and P, the Zl invariant δ of 2M particle-hole symmetric bands εM−1(k) · · · ε−1(k), ε1(k) · · · εM(k) is related to the number of Dirac points NL between ε−1(k) and ε1(k) in the first Brillouin zone (BZ) as δ = NL 2 mod 2, provided that the 2M bands are gapped from higher and lower bands. Here εn(k) (ε−n(k)) is the n-th positive (negative) band. Therefore, as long as 4l + 2 (l ∈ N) Dirac points exist between ε−1(k) and ε1(k) we find that 2M, ∀M ∈ N particle-hole symmetric bands (separate in energy from the M + 1, M + 2, . . . , M + 2, M − 1, . . . , M − 1, M − 2, . . . , M bands) have δ = 1 and hence are topologically nontrivial. The feature of TBG that arbitrary 2M bands are topological is inconsistent with lattice models with C2zT and P symmetry. In a lattice model, if 2M is large enough, e.g., equals to the number of orbitals in the model, the 2M bands have to be topologically trivial because they span the Hilbert space of the local orbitals. Therefore, the Z2 topology, and the 4l + 2 Dirac points accordingly,

∗ bernevig@princeton.edu
cannot be realized in lattice models with finite number of orbitals. We hence call the \( \mathbb{Z}_2 \) topology an anomaly of the \( C_2 \times T \) and \( \mathcal{P} \) symmetries. We further note that this implies that the many-body \( U(4) \) and \( U(4) \times U(4) \) symmetries [111–113] are incompatible with a lattice model and hence anomalous. It also implies that the lattice models build to model TBG [19, 52, 53, 55] have to break the \( \mathcal{P} \) symmetry or the \( C_2 \times T \) symmetry of the TBG model.

This paper is organized as follows. In Section II, we present a review of the BM model of TBG and summarize its symmetries. The error of the approximate particle-hole symmetry \( \mathcal{P} \) is defined and is confirmed as being small \((<0.01)\). In Section III, we prove that the \( \mathcal{P} \) symmetry protects a stable \( \mathbb{Z}_2 \) topological state. In Section IV, a no-go theorem of the \( \mathbb{Z}_2 \) topological state is proved for lattice models with the \( C_2 \times T \) symmetry or the \( \mathcal{P} \) symmetries. The relation between the \( \mathbb{Z}_2 \) invariant and the number of Dirac points is also established in this section. In Section V, we show that, when the two flat bands are gapped from the other bands, there is natural choice of Chern band basis (with opposite Chern numbers) in the two flat bands. The Chern band basis is used in our interacting works [111–114] on TBG. In Section VI, we show that, in the so-called second chiral limit, defined in [111] as the second limit having an interacting extended \( U(4) \times U(4) \) symmetry, the symmetry anomaly of TBG manifests as a perfect metal phase, where all the bands are connected to each other. A brief summary of this work is given in Section VII.

II. The BM model of twisted bilayer graphene and its symmetries

We first present a short review of the BM model. A more detailed account can be found in supplementary material of Ref. [56].

A. A brief review of the BM model

TBG is an engineered material of two graphene layers twisted by a small angle \( \theta \) from each other. The band structure of each of the two layers exhibits two Dirac points at the \( K \) and \( K' \) momenta in the single layer Brillouin zone (BZ), respectively; the two Dirac points are related by time-reversal \( T \). Thus the band structure of TBG exhibits four Dirac points: two from the top layer and the other two from the bottom layer. When \( \theta \) is small such that the interlayer coupling is smooth in real space - with a length scale much larger than the atom distances - the graphene valley \((K \text{ and } K')\) is a good quantum number of low energy states of TBG [1]. In this case, the states around \( K \) (\( K' \)) in the top layer only couple to the states around \( K \) (\( K' \)) in the bottom layer. Therefore, the low energy band structure of TBG decomposes into two independent graphene valleys, and each valley has two Dirac points originated from the two layers, respectively.

In this work, we will focus on the valley \( K \). The bands in the other valley \( K' \) can be obtained by acting \( T \) on the bands in the valley \( K \).

We assume the top single graphene layer is rotated from the \( x \)-direction by an angle \( \frac{\theta}{2} \) (rotation axis is \( z \)). Thus the Dirac Hamiltonian around \( K \) in the top layer is

\[ -i v_F \partial_x (\cos \frac{\theta}{2} \sigma_x - \sin \frac{\theta}{2} \sigma_y) - i v_F \partial_y (\cos \frac{\theta}{2} \sigma_y + \sin \frac{\theta}{2} \sigma_x) \approx -i v_F \partial_x \cdot \sigma + i \frac{\theta}{2} v_F \partial_x \times \sigma, \]

where \( v_F \) is the Fermi-velocity of single-layer graphene and \( \sigma = (\sigma_x, \sigma_y) \) are Pauli matrices representing the \( A/B \) sublattices of graphene. The bottom layer is rotated from the \( x \)-direction by an angle \( -\frac{\theta}{2} \).

Correspondingly, the Dirac Hamiltonian around \( K \) in the bottom layer is \(-i v_F \partial_x \cdot \sigma - i \theta v_F \partial_x \times \sigma\). The interlayer coupling is encoded in a position dependent matrix \( T(r) \), where \( r = (x, y) \), such that the Hamiltonian of TBG, to linear order of \( \theta \), can be written as

\[
H(r) = -i v_F \left( \tau_0 \partial_x - \frac{\theta}{2} \tau_z \partial_x \times \sigma \right) + \left( \begin{array}{cc} 0 & T(r) \\ T^\dagger(r) & 0 \end{array} \right) \quad \text{(1)}
\]

Here \( \tau_0 \) and \( \tau_z \) are the two-by-two identity matrix and the third Pauli matrix for the layer degree of freedom, respectively. According to Ref. [1], when \( \theta \) is small \((\sim 1^\circ)\), \( T(r) \) forms a smooth moirépotential:

\[
T(r) = \sum_{i=1}^{3} e^{-i q_i \cdot r} T_i, \quad \text{(2)}
\]

where \( q_i \)'s are \( q_1 = k_D (0, -1) \), \( q_2 = k_D (\frac{\sqrt{3}}{2}, \frac{1}{2}) \), \( q_3 = k_D (-\frac{\sqrt{3}}{2}, \frac{1}{2}) \), with \( k_D = 2 |K| \sin \frac{\theta}{2} \) being the distance between \( K \) momenta in the two layers, and \( T_i \)'s are

\[
T_i = w_0 \sigma_0 + w_1 \left[ \sigma_x \cos \frac{2 \pi (i+1)}{3} + \sigma_y \sin \frac{2 \pi (i+1)}{3} \right], \quad \text{(3)}
\]

where \( w_0 \) and \( w_1 \) are two constant parameters. Since the \( w_0 \) term contributes to the diagonal elements, it represents the interlayer coupling between the \( A(B) \) sublattice of the top layer and the \( A(B) \) sublattice of the bottom layer. Similarly, the \( w_1 \) term only contributes to the off-diagonal elements, it is thus associated to the interlayer coupling between \( A(B) \) sublattice of the top layer and \( B(A) \) sublattice of the bottom layer.

The moirépotential (Eq. (2)) is invariant (up to a gauge transformation) under the translations \( a_{M1} = \frac{2 \pi}{k_D} (1, \frac{1}{3}) \), \( a_{M2} = \frac{2 \pi}{k_D} (-\frac{1}{3}, \frac{1}{3}) \). The translation symmetry of the moirépotential is manifest in real space (Fig. 1a). The corresponding reciprocal lattice bases are \( b_{M1} = q_2 - q_1 \), \( b_{M2} = q_3 - q_1 \) (Fig. 1b). The unit cell spanned by \( a_{M1} \) and \( a_{M2} \) is referred to as the moiréunit cell. Each moiréunit cell has one AA region, one AB region, and one BA region. In the AA region, the \( A(B) \) sublattice of the top layer sit on top of the \( A(B) \) sublattice of the bottom layer; in the AB region, the \( A \) and \( B \) sublattices of the top layer sit on top of the \( B \) sublattices and the empty hexagon centers of the bottom layer, respectively; in the BA region, the \( B \) and \( A \) sublattices of the upper layer sit on top of the \( A \) sublattices and the
empty hexagon centers of the lower layer, respectively. First principle calculations show that the two layers are corrugated in the z-direction [120–123]. The distance between the two layers in the AA region is larger than the distance in the AB and BA regions. Since \( w_0 \) and \( w_1 \) are mainly dominated by the couplings in the AA and AB/BA regions [1], respectively, this implies that, in the realistic model, \( w_0 \) is smaller than \( w_1 \) [53]. In Figs. 1d and 1f, we show the the band structures for two different twist angles \( \theta = 1.05^\circ, 0.7^\circ \). The parameters are set as \( v_F = 5.944\text{eV} \cdot \text{Å}, |K| = 1.703\text{Å}^{-1}, w_1 = 110\text{meV}, w_0 = 0.7w_1 \).

### B. Symmetries of the BM model

The model Eq. (1) has several point group symmetries: (i) \( C_{2z}T = \sigma_zK \), where \( K \) is the complex conjugation, (ii) \( C_{3z} = e^{i\frac{2\pi}{3}\sigma_z} \), (iii) \( C_{2x} = \tau_x\sigma_x \). One can verify that the Hamiltonian is invariant under these symmetries. Notice that the single-graphene-valley Hamiltonian does not have the \( C_{2z} \) rotation and the time-reversal \( T \) symmetries since they map one graphene valley to the other. The three crystalline symmetries and the moirétranslations generate the magnetic space group \( P6^22'2' \) (#177.151 in the BNS setting [124]) [56].

We define a unitary particle-hole operation \( P = i\tau_y \), which transforms the position as \( r \rightarrow -r \) [56]. Here \( \tau_x,\tau_y,\tau_z \) are Pauli matrices representing the layer degree of freedom. Under \( P \) the Hamiltonian transforms as

\[
P H(r) P^\dagger = -H(-r) + i\theta v_F \tau_z \partial_x \times \sigma.
\] (4)

The second term on the right hand side is in linear order of \( \theta \). It approaches zero when \( \theta \rightarrow 0 \). While the other terms in \( H(r) \) do not vanish in the \( \theta \rightarrow 0 \) limit. Thus it is safe to ignore this term in the small angle limit. To be specific, when \( \theta \sim 1^\circ \), this term is of order \( 0.018v_F k_D \) and hence is much smaller than the energy scale of the low energy physics, which is of order \( v_F k_D \). Therefore, \( P \) is an emergent anticommuting symmetry when \( \theta \) is small. It satisfies the algebra [56]:

\[
[C_{2z}T, P] = [C_{3z}, P] = 0, \quad (C_{2x}, P) = 0, \quad P^2 = -1.
\] (5)

For later convenience, we define an anti-unitary particle operation \( \mathcal{P} = PC_{2z}T = i\tau_y\sigma_x K \), which is local in real space and satisfies \( \mathcal{P}^2 = -1 \). It acts on the Hamiltonian as

\[
\mathcal{P} H(r) \mathcal{P}^{-1} = -H(r) + i\theta v_F \tau_z \partial_x \times \sigma.
\] (6)
As discussed in details in Appendix B, the \( \mathbf{k} \)-dependence in the interlayer coupling may also cause a breaking of the emergent \( \mathcal{P} \) symmetry. We can also define a chiral operation \( \mathcal{C} = \sigma_z \), which is local in real space. \cite{58}. Under \( \mathcal{C} \) the Hamiltonian transforms as

\[
\mathcal{C} \mathcal{H}(\mathbf{r}) \mathcal{C}^\dagger = -\mathcal{H}(\mathbf{r}) + 2w_0 \tau_x \sigma_0 \sum_{i=1}^{3} e^{-i\mathbf{a}_i \cdot \mathbf{r}}.
\]

(7)

In the so-called chiral limit \cite{58}, i.e., \( w_0 = 0 \), the second term on the right hand side vanishes and hence \( \mathcal{C} \) become an emergent anticommuting symmetry. The chiral symmetry satisfies the algebra

\[
\{ \mathcal{C}_2 \mathcal{T}, \mathcal{C} \} = \{ \mathcal{C}_2, \mathcal{C} \} = 0, \quad [\mathcal{C}_3, \mathcal{C}] = [\mathcal{P}, \mathcal{C}] = 0, \quad \mathcal{C}^2 = 1.
\]

(8)

We numerically checked how much \( \mathcal{P} \) and \( \mathcal{C} \) are broken in the wavefunctions of the model Eq. (1). To be specific, we define the errors of the two symmetries in the two flat bands as

\[
\text{error}(\mathcal{P}) = 1 - \frac{1}{\Omega_M} \int d^2k |\langle u_{1-\mathbf{k}}|\mathcal{P}|u_{1, \mathbf{k}} \rangle|^2, \quad (9)
\]

\[
\text{error}(\mathcal{C}) = 1 - \frac{1}{\Omega_M} \int d^2k |\langle u_{1, \mathbf{k}}|\mathcal{C}|u_{1-\mathbf{k}} \rangle|^2, \quad (10)
\]

respectively, where \( |u_{1-\mathbf{k}}\rangle \) and \( |u_{1, \mathbf{k}}\rangle \) are the periodic parts of the Bloch states of the highest occupied band and the lowest empty band at charge neutrality, respectively, and \( \Omega_M = |\mathbf{b}_{M1} \times \mathbf{b}_{M2}| = \frac{3\sqrt{3}}{2} \lambda^2 \) is the area of the Moire Brillouin zone. When the two symmetries are exact, we have \( |\langle u_{1-\mathbf{k}}|\mathcal{P}|u_{1, \mathbf{k}} \rangle| = |\langle u_{1, \mathbf{k}}|\mathcal{C}|u_{1-\mathbf{k}} \rangle| = 1 \) and hence the errors are zero. Using the parameters \( v_F = 5.933\text{eV} \cdot \text{Å}, |K| = 1.703\text{Å}^{-1}, w_1 = 110\text{meV} \), we plot error(\( \mathcal{P} \)) and error(\( \mathcal{C} \)) as functions of \( w_0/w_1 \) (with fixed \( w_1 \)) for a few twist angles in Fig. 2. For \( \theta = 1.05^\circ \), error(\( \mathcal{P} \)) is small \((< 0.01)\) for \( w_0 \leq 0.82w_1 \), thus the \( \mathcal{P} \) symmetry is a good approximation for TBG, while the \( \mathcal{C} \) symmetry only starts being good \((\text{with error} < 0.01)\) for \( w_0 \leq 0.07w_1 \).

III. Stable topology protected by particle-hole symmetry \( \mathcal{P} \)

A. The Wilson loop \( \mathbb{Z}_2 \) invariant protected by \( \mathcal{P} \)

We denote the Hamiltonian in momentum space as \( \mathcal{H}(\mathbf{k}) \). We assume the emergent anti-unitary particle-hole symmetry, i.e., \( \mathcal{P}\mathcal{H}(\mathbf{k})\mathcal{P}^{-1} = -\mathcal{H}(\mathbf{k}) \), and \( \mathcal{P}^2 = -1 \). As detailed in Section II B, \( \mathcal{P} = \mathcal{P}_{C2z}\mathcal{T} \) is anti-unitary and squares to -1, and is the product of the unitary \( \mathcal{P} \) of Ref. \cite{56} and \( \mathcal{C}_{2z}\mathcal{T} \). We denote the energy and the periodic part of Bloch state of the \( n \)-th band above (below) the zero energy as \( \epsilon_n(\mathbf{k}) \) \( (\epsilon_{-n}(\mathbf{k})) \) and \( |u_n(\mathbf{k})\rangle \( (|u_{-n}(\mathbf{k})\rangle) \), respectively. As explained in Appendix A and in Ref. \cite{56}, \( |u_n(\mathbf{k})\rangle \) satisfies the periodicity \( |u_n(\mathbf{k} + \mathbf{G})\rangle = V^G|u_n(\mathbf{k})\rangle \), with \( \mathbf{G} \) being a reciprocal lattice and \( V^G \) a unitary matrix referred to as the embedding matrix. Since \( \mathcal{P} \) anti-commutes with the Hamiltonian and flips the momentum, we have \( \epsilon_n(\mathbf{k}) = -\epsilon_{-n}(\mathbf{k}) \). The state \( |\mathcal{P}|u_n(\mathbf{k})\rangle \) must have the momentum \( -\mathbf{k} \) and the energy \( \epsilon_{-n}(\mathbf{k}) \). In general, \( |\mathcal{P}|u_n(\mathbf{k})\rangle \) is spanned by Bloch states at \( -\mathbf{k} \)

\[
|\mathcal{P}|u_{n}(\mathbf{k})\rangle = \sum_{n'} |u_{n'}(-\mathbf{k})\rangle B_{n'n}(\mathbf{k}),
\]

(11)

where the summation over \( n' \) is limited to those satisfying \( \epsilon_{n'}(\mathbf{k}) = -\epsilon_{-n}(\mathbf{k}) \), and \( B_{n'n}(\mathbf{k}) \) is a unitary matrix referred to as the sewing matrix of \( \mathcal{P} \). \( B_{n'n}(\mathbf{k}) \) is periodic in momentum space, i.e., \( B_{n'n}(\mathbf{k} + \mathbf{G}) = B_{n'n}(\mathbf{k}) \). Since \( \mathcal{P}^2 = -1 \), it should satisfy

\[
B_{n'n}(\mathbf{k}) B_{n'n}^\dagger(\mathbf{k}) = -1.
\]

(12)

Multiplying \( B_{n'n}(\mathbf{k})^\dagger \) on the right hand side of the above equation, we obtain

\[
B_{n'n}(\mathbf{k}) = -B_{n'n}^\dagger(\mathbf{k} + \mathbf{G}^\dagger) B_{n'n}(\mathbf{k}).
\]

(13)

We now prove that the \( \mathcal{P} \) symmetry protects a \( \mathbb{Z}_2 \) invariant for \( 2M \) particle-hole symmetric separate bands, i.e., bands \( \epsilon_{-M}(\mathbf{k}), \epsilon_{-M+1}(\mathbf{k}) \cdots \epsilon_{M}(\mathbf{k}) \), gapped from higher and lower bands. This proof is not limited to TBG but applies to any system having our anti-unitary \( \mathcal{P} \) symmetry. We introduce the matrix \( \mathcal{U}(\mathbf{k}) = (|u_{-M}(\mathbf{k})\rangle, |u_{-M+1}(\mathbf{k})\rangle \cdots |u_M(\mathbf{k})\rangle) \). We parameterize \( \mathbf{k} \) as \( k_1 \mathbf{b}_1 + k_2 \mathbf{b}_2 \), where \( \mathbf{b}_1 \) and \( \mathbf{b}_2 \) are the reciprocal lattice basis vectors. Then we define the Wilson loop operator of the \( 2M \) bands for a given \( k_1 \) as

\[
W(k_1) = \lim_{N \to \infty} \prod_{j=0}^{N-1} U_j^\dagger(k_1, j) U(k_1, (j+1) 2\pi/N).
\]

(14)

The order of the matrices in the product is given by \( j \): matrices with larger \( k_2 \) \( (= j 2\pi/N) \) always appear on
Since $W(k_1)$ is periodic at $k_1$, $W(k_1)$ with $k_1 = 0, \pi$ are invariant under the particle-hole operation:

$$W(k_1) = B^{(P)T}(k_1, 0)W^T(-k_1)B^{(P)*}(k_1, 0), \quad (k_1 = 0, \pi).$$

(17)

It is this invariance that protects degeneracies of Wilson loop bands at $k_1 = 0, \pi$. To see this, we parameterize the unitary matrix $W(k_1)$ as $e^{iH(k_1)}$ with $H(k_1)$ being a hermitian matrix periodic in $k_1$, called the Wilson Hamiltonian. The eigenvalues of $H(k_1)$ form the Wilson loop bands. We can define the particle-hole operator for $H(k_1)$ as $\tilde{P}(k_1) = B^{(P)T}(k_1, 0)K$ such that Eq. (16) can be written as $H(k_1) = \tilde{P}(-k_1)H(-k_1)\tilde{P}^{-1}(-k_1)$. We have $\tilde{P}(k_1)\tilde{P}(-k_1) = -I$ due to Eq. (12). It is worth noting that unlike the Hamiltonian $H(k)$ which anti-commutes with $P$, $H(k_1)$ commutes with $\tilde{P}$. Because $\tilde{P}^2(k_1) = -I$ and $[\tilde{P}, H(k_1)] = 0$ for $k_1 = 0, \pi$, the Wilson loop bands - the eigenstates of the Wilson Hamiltonian - at $k_1 = 0, \pi$ form doublets due to the Kramers theorem.

The $\mathbb{Z}_2$ invariant $\delta$ is defined such that $\delta = 1$ if the Wilson loop bands form a zigzag flow between $k_1 = 0$ and $k_1 = \pi$ - equivalent to a Quantum Spin Hall flow of Kramers paired Wannier centers, and $\delta = 0$ otherwise. Examples of $\delta = 1$ and $\delta = 0$ with only $P$ symmetry are shown in Figs. 3a and 3b, respectively. Fig. 3a does not contain the $C_{2z}T$ symmetry and is meant to depict the possible cases with only our anti-unitary $P$ symmetry. Because the degeneracies at $k_1 = 0, \pi$ are protected by $P$, a zigzag flow is stable against adding $P$-preserving bands as long as these bands are topologically trivial (they do not exhibit Wilson loop flow themselves) that do not close the gaps between the $2M$ bands and the higher/lower bands (Fig. 3a-c).

In Figs. 1c and 1g, we plot the Wilson loop bands of the middle two bands ($\epsilon_{-1}(k), \epsilon_{1}(k)$) of TBG with $\theta = 1.05^\circ$ and the Wilson loop bands of the middle ten bands ($\epsilon_{-5}(k)\cdots \epsilon_{5}(k)$) of TBG with $\theta = 0.7^\circ$, respectively. Both have the zigzag flow and hence have $\delta = 1$. We do not plot the Wilson loop bands of the middle ten bands of TBG with $\theta = 1.05^\circ$ because they have touching points with higher/lower bands at generic momenta (away from high symmetry lines).

B. Comparison of the $P$-protected topology and $C_{2z}T$-protected topology

In Ref. [56], some of the authors of the present work proved that the $C_{2z}T$ symmetry protects the Wilson loop flow for two bands, as shown in Fig. 3d, where the crossings at $\lambda = 0, \pi$ are protected by $C_{2z}T$. The Wilson loop flow is characterized by an integer-valued invariant $e_2$: the winding number of a smooth branch of the Wilson loop bands. There is a gauge ambiguity for the sign of $e_2$. For example, the Wilson loop bands in Fig. 3d has $e_2 = 1$ if we choose the branch going up to define the winding number and $e_2 = -1$ if we choose the branch going down. $e_2$ is also referred to as the Euler's class [54], as
will be briefly introduced in Section V. With only $C_{2z}T$ symmetry, the flow can be broken by adding two trivial (flat) Wilson loop bands, as shown in Fig. 3d-f, since the crossings at generic positions - different from $\lambda = 0, \pi$ in the Wilson loop spectrum are not protected by $C_{2z}T$. After the Wilson loop bands are gapped, one can still define a $C_{2z}T$-protected $Z_2$ invariant through the nested Wilson loop [54, 56]. Nevertheless, this $C_{2z}T$-protected $Z_2$ invariant does not correspond to Wannier obstruction [54, 55]. Therefore, the topology protected only by $C_{2z}T$ is fragile. Ref. [56] showed that, by adding the unitary particle-hole symmetry $P$, one cannot render the Stiefel–Whitney index trivial by adding more bands; however, nontrivial Stiefel-Whitney index does not imply non-Wannierizable bands, and hence [56] called the index “stable”, between quotation marks; this paper removes the quotation marks by proving non-wannierizability.

On the contrary, with the $P$ symmetry, we cannot break the zigzag flow by adding trivial (non-winding) Wilson loop bands, just like in the Quantum Spin Hall problem. First, due to the Kramers degeneracy guaranteed by $P$, a trivial state must have at least two Wilson loop bands - corresponding to the fact that, with particle-hole symmetry, we must add to the nontrivial bands, generically, two bands - of some energy $\pm E$. The two Wilson loop bands are separated at generic $k_1$ but degenerate at $k_1 = 0, \pi$, as shown in Fig. 3b. If we couple such a two-band trivial state to the topological state, the total Wilson loop bands are still gapless (Fig. 3c) since the degeneracies at $k_1 = 0, \pi$ are protected. Therefore, the topology protected by $P$ is stable.

If a two-band system has both $C_{2z}T$ and $P$ symmetries, the $Z_2$ invariant protected by $P$ is given by the parity of $e_2$, i.e., $\delta = e_2$ mod 2. For example, the Wilson loop bands in Fig. 1e has $e_2 = 1$ and $\delta = 1$. Therefore, the topology protected by $P$ is stable. This is the simplest topological state in systems with $C_{2z}T$ and $P$ symmetries. Hence, this is the topologically nontrivial class of this symmetry.

C. An alternative expression of the $Z_2$ invariant

We have mentioned that the zigzag flow of the Wilson loop bands protected by $P$ is same as the zigzag flow of Wilson loop bands protected by the time-reversal symmetry in 2D Quantum Spin Hall topological insulator [127]. Now we show that they are indeed equivalent. Suppose $H(k)$ have the $P$ ($P^2 = 1$) symmetry, i.e., $H(k) = -PH_-(k)P^{-1}$, then we define the squared Hamiltonian as $H^2(k) = H(k) \cdot H(k)$ such that it commutes with $P$, i.e., $H^2(k) = PH^2_-(k)P^{-1}$. We can regard $P$ as a “time-reversal symmetry” of $H^2(k)$. An eigenstate of $H(k)$ with the energy $\epsilon_n(k)$ is still an eigenstate of $H^2(k)$ but has the squared energy $\epsilon_n^2(k)$. States of the 2M particle-hole-symmetric bands used to define the Wilson loop (Eq. (14)), i.e., $|u_{-M}(k)\rangle \cdots |u_M(k)\rangle$, form the lowest 2M bands of the squared Hamiltonian $H^2(k)$. Thus the Wilson loop operator of the 2M particle-hole symmetric bands of $H(k)$ is same as the Wilson loop operator of the 2M lowest bands of $H^2(k)$. The zigzag flow of the Wilson loop can be equivalently thought as protected by the “time-reversal symmetry” of $H^2(k)$.

The time-reversal-protected $Z_2$ invariant can be alternatively expressed as a topological obstruction [129, 130]. Consider 2M bands $\{|u_0^I(k)\rangle, |u_0^J(k)\rangle\}$, and $n = 1 \cdots M$ in a time-reversal ($T$) symmetric system that satisfy the gauge condition $|u^I_n(k)\rangle = T|u^I_n(k)\rangle$, $|u^J_n(-k)\rangle = -T|u^J_n(k)\rangle$, then the corresponding $Z_2$ invariant is given by

$$\delta = \frac{1}{2\pi} \left( \oint_{\mathcal{B}} dk \cdot A(k) - \int_{\mathcal{B}} d^2k \Omega(k) \right) \mod 2, \quad (18)$$

where $\mathcal{B}$ is half of the BZ whose boundary $\partial\mathcal{B}$ is $P$-invariant,

$$A(k) = i \sum_{n=1}^{M} \sum_{a=I,J} \langle u^a_n(k)|\partial_k u^a_n(k) \rangle \quad (19)$$

is the Berry’s connection of the considered bands, and $\Omega(k) = \partial_k \times A(k)$ is the Berry’s curvature. An example of $\mathcal{B}$ is shown in Fig. 4. We regard $|u_{-M}(k)\rangle \cdots |u_M(k)\rangle$ as the lowest 2M bands of $H^2(k)$ and $P$ the “time-reversal symmetry” of $H^2(k)$. If we impose the gauge $|u_{-n}^I(-k)\rangle = T|u_{n}^I(k)\rangle$ ($n = 1 \cdots M$), i.e., choose the sewing matrix defined in Eq. (11) as $B_{n,n}^{P}(k) = \delta_{n,n}^{I,J} \text{sgn}(n)$, then we can regard $|u_{n}^I(k)\rangle$ and $|u_{-n}^I(k)\rangle$ as $|u_{n}^J(k)\rangle$ and $|u_{n}^J(k)\rangle$, respectively. Thus the $Z_2$ invariant of the 2M bands of $H(k)$ protected by $P$ is given by Eq. (18). This expression will be used for one of the ways to prove the symmetry anomaly of 4l+2 Dirac points in systems with $C_{2z}T$ and $P$ symmetries (See Section IV).

IV. A no-go theorem of two Dirac fermions on lattices with $C_{2z}T$ and $P$ symmetries

In this section, we will prove that if there are 4l+2 ($l \in \mathbb{N}$) Dirac fermions at zero energy (chemical potential) in a system with $C_{2z}T$ and $P$ symmetries, then the $Z_2$ invariant of the 2M bands (arbitrary $M$) above and below the chemical potential, i.e., $\epsilon_{-M}(k) \cdots \epsilon_M(k)$, is guaranteed to be 1, provided that the 2M bands are gapped from other bands. As a consequence, for arbitrary $M$, the 2M particle-hole symmetric bands are not Wannierizable. That means the 4l+2 Dirac fermions do not have a lattice support.

Before going into a mathematical proof, first we give an intuitive proof that the Wilson loop of a $C_{2z}T$ and $P$
system with \(4l + 2\) Dirac fermions at zero energy needs to wind. We first assume that we have 2 bands separate from other bands close to charge neutrality. In [44, 54] it was shown that the number of Dirac points in half BZ mod 2 equals the winding of the Wilson loop. For \(4l + 2\) Dirac nodes in between these two bands, the winding would be odd, as in Fig. 1e. Adding non-zero trivial or nontrivial energy bands to this system would happen in pairs; introducing a set (trivial, due to \(\tau\) adding trivial bands or pairs of nontrivial bands to any single band topologically trivial) bands at non-zero energy would have its \(\mathcal{P}\) conjugate and appear in numbers \(2n\). Introducing nontrivial bands at nonzero energy would mean introducing \(2 \times 2n\) bands into the system, as any possible nontrivial set of bands at a given energy comes as a multiple of 2. These bands can introduce only a multiple of 4 number of Dirac fermions into the system: each set of two separate bands has to have a multiple of 2 Dirac fermions. From our Quantum Spin Hall (QSH) experience, whatever number of bands we introduce on top of our nontrivial bands with \(4l + 2\) Dirac fermions cannot change the Wilson loop winding, as we are either adding trivial bands or pairs of nontrivial bands to a QSH system. Hence the winding (of the \(4n + 2\) Dirac fermion band) is stable to the addition of any bands respecting \(C_{2z}T\) and \(\mathcal{P}\). The only way the winding can be interrupted is by the addition of one set of 2 bands with Wilson loop winding to the already existent Wilson loop winding 2-bands. However, since with \(C_{2z}T\) the number of Dirac nodes mod 4 is equal to twice times the winding, this additional one set of 2-bands would bring about another \(4l + 2\) Dirac points so the full system would have a number of Dirac fermions divisible by 4. Hence a system with \(4l + 2\) Dirac fermions and \(C_{2z}T\) and \(\mathcal{P}\) has to exhibit Wilson loop winding.

Now, by making use of Eq. (18), we give another proof that \(2M\) bands (gapped from other bands) with \(C_{2z}T\) and \(\mathcal{P}\) symmetries that have \(4l + 2\) Dirac points between \(\epsilon_{-1}(k)\) and \(\epsilon_{1}(k)\) must have a nontrivial topology. Due to the \(C_{2z}T\) symmetry, the Bloch states satisfy

\[
C_{2z}T|u_n(k)\rangle = \sum_{n'} |u_{n'}(k)\rangle B_{u_{n'}^{(C_{2z}T)}}(k),
\]

where \(B_{u_{n'}^{(C_{2z}T)}}(k)\) is unitary and called the \(C_{2z}T\) sewing matrix. The summation over \(n'\) is limited to values satisfying \(\epsilon_{n'}(k) = \epsilon_n(k)\). Substituting this constraint into the definition of the Berry’s curvature \(\Omega(k)\), we find that \(\Omega(k) = 0 \ [44, 54, 80]\). Thus we only need to evaluate the first term on the right hand side of Eq. (18). We define

\[
\mathbf{A}'(k) = i \sum_{n=1}^{M} \langle u_n(k)|\partial_k u_n(k)\rangle \text{ for the positive bands}
\]

and \(\mathbf{A}''(k) = i \sum_{n=1}^{M} \langle u_{-n}(k)|\partial_k u_{-n}(k)\rangle \) for the negative bands. The total Berry’s connection is \(\mathbf{A} = \mathbf{A}' + \mathbf{A}''\). By imposing the gauge condition \(|u_{-n}(-k)\rangle = \mathcal{P}|u_n(k)\rangle\) \((n = 1 \cdots M)\) required by Eq. (18), we find

\[
\begin{align*}
\mathbf{A}'(k) &= i \sum_{n=1}^{M} \langle u_{-n}(k)|\partial_k u_{-n}(k)\rangle \\
&= i \sum_{n=1}^{M} (\partial_k \mathcal{P} u_{-n}(k))|\mathcal{P} u_{-n}(k)\rangle = i \sum_{n=1}^{M} \langle \partial_k u_{n}(-k)|u_{n}(-k)\rangle \\
&= -i \sum_{n=1}^{M} (u_n(-k)|\partial_k u_{n}(-k)\rangle = \mathbf{A}'(-k),
\end{align*}
\]

where we have applied the property of anti-unitary symmetry introduced below Eq. (15). Since the boundary \(\partial \mathcal{B}\) (Fig. 4) is invariant under \(k \rightarrow -k\), the integrals of \(\mathbf{A}'(k)\) and \(\mathbf{A}''(k)\) are equal, i.e.,

\[
\oint_{\partial \mathcal{B}} dk \cdot \mathbf{A}'(k) = \oint_{\partial \mathcal{B}} dk \cdot \mathbf{A}''(k).
\]

The \(C_{2z}T\) symmetry stabilizes 2D Dirac points [131], and each Dirac point between the positive bands and the negative bands contribute to a \(\pi\) or \(-\pi\) Berry’s phase of \(\mathbf{A}'(k)\) (Fig. 4). Due to the \(\mathcal{P}\) symmetry \(\epsilon_{-1}(-k) = -\epsilon_{n}(k)\), the Dirac points must be equally distributed in \(\mathcal{B}\) and its complementary set \(\mathcal{B} - \mathcal{B}\). Hence if there are \(4l + 2\) Dirac points in the BZ, there will be \(2l + 1\) Dirac points in \(\mathcal{B}\) and we have \(\oint_{\partial \mathcal{B}} dk \cdot \mathbf{A}'(k) = (2l + 1)\pi \mod 2\pi\). According to Eq. (22), we have

\[
\oint_{\partial \mathcal{B}} dk \cdot (\mathbf{A}'(k) + \mathbf{A}''(k)) = (4l + 2)\pi \mod 4\pi.
\]

Substituting this equation into Eq. (18) and using the fact that \(\Omega(k) = 0\), we obtain \(\delta = 1\). Thus the presence of \(4l + 2\) Dirac points in a system with \(C_{2z}T\) and \(\mathcal{P}\) symmetries implies a nontrivial topology. In contrast to lattice models whose whole bands are trivial, this nontrivial topology is guaranteed by the Dirac points between \(\epsilon_1(k)\) and \(\epsilon_{-1}(k)\) and hence cannot be trivialized by adding higher and lower energy bands (preserving \(\mathcal{P}\)). Therefore, no matter how many high energy bands are included, as long as they respect \(C_{2z}T\) and \(\mathcal{P}\), the considered bands must have nontrivial topology. As will be shown in next paragraph, in a lattice model with a finite number of orbitals per unit cell, the Wilson loop

\[
\oint_{\partial \mathcal{B}} dk \cdot (\mathbf{A}'(k) + \mathbf{A}''(k)) = (4l + 2)\pi \mod 4\pi.
\]

Substituting this equation into Eq. (18) and using the fact that \(\Omega(k) = 0\), we obtain \(\delta = 1\). Thus the presence of \(4l + 2\) Dirac points in a system with \(C_{2z}T\) and \(\mathcal{P}\) symmetries implies a nontrivial topology. In contrast to lattice models whose whole bands are trivial, this nontrivial topology is guaranteed by the Dirac points between \(\epsilon_1(k)\) and \(\epsilon_{-1}(k)\) and hence cannot be trivialized by adding higher and lower energy bands (preserving \(\mathcal{P}\)). Therefore, no matter how many high energy bands are included, as long as they respect \(C_{2z}T\) and \(\mathcal{P}\), the considered bands must have nontrivial topology. As will be shown in next paragraph, in a lattice model with a finite number of orbitals per unit cell, the Wilson loop

\[
\oint_{\partial \mathcal{B}} dk \cdot (\mathbf{A}'(k) + \mathbf{A}''(k)) = (4l + 2)\pi \mod 4\pi.
\]
bands of the whole bands must be trivial. Therefore, $4l + 2$ Dirac points cannot be realized in lattice models because the corresponding band structure, no matter how many high and low energy bands are considered, must be topologically nontrivial.

Here we show that the whole bands of a lattice model must be trivial. Let the lattice model has $N$ orbitals, then the $U(k)$ matrix entering the Wilson loop operator (Eq. (14)) of the whole bands is $U(k) = (|u_1(k)| \cdots |u_N(k)|)$. By the completeness of all the Bloch states we have $U(k)U^\dagger(k) = 1$. Thus the Wilson loop operator in Eq. (14) is $W(k_1) = U^\dagger(k_1)U(k_1, 2\pi) = U^\dagger(k_1, 0)V^{(0, 2\pi)}U(k_1, 0)$, where $V^{(0, 2\pi)}$ is the embedding matrix defined in Appendix A (with $G = 2\pi b_2$). Since $U(k_1, 0)$ is an $N \times N$ unitary matrix, the eigenvalues of $W(k_1)$ are same as eigenvalues of $V^{(0, 2\pi)}$ and hence do not change with $k_1$ and do not wind.

It is worth noting that, in TBG, the symmetry anomaly does not depend on the parameters of the Hamiltonian Eq. (1). In the weak coupling limit ($u_0 \ll v_F k_D, w_1 \ll v_F k_P$), we have two Dirac points at $K_M$ and $K'_M$ in the moiréBZ. If the $2M$ bands $\epsilon_{-M}(k) \cdots \epsilon_M(k)$ are gapped from the other bands, the $2M$ bands must be topological due to correspondence between the number of Dirac points and the $\mathbb{Z}_2$ invariant $\delta$. Tuning the parameters of TBG may couple the $2M$ bands to higher bands $\epsilon_{M+1}(k) \cdots \epsilon_{M'}(k)$ ($M' > M$) and lower bands $\epsilon_{-M'}(k) \cdots \epsilon_{-M-1}(k)$, which are assumed be gapped from $\epsilon_{M'+1}(k)$ and $\epsilon_{-M-1}(k)$ as we tune the parameters. In the weak coupling limit, the additional $2M'-2M$ bands must have $\delta = 0$ since they do not have Dirac points between $\epsilon_{-M-1}(k)$ and $\epsilon_{M+1}(k)$. Therefore, after we couple the $2M$ bands to the $2M'$-2M bands, the $2M'$ bands as a whole will have $\delta = 1 + 0 = 1$. As we tune the parameters, additional Dirac points between $\epsilon_1(k)$ and $\epsilon_{-1}(k)$ may be created due to gap closing and reopening between $\epsilon_1(k)$ and $\epsilon_{-1}(k)$. However, the total number of Dirac points between $\epsilon_1(k)$ and $\epsilon_{-1}(k)$ must equal to $2$ mod $4$, i.e., $4l + 2$ ($l \in \mathbb{N}$), because the topological invariant of the $2M'$ bands is guaranteed to be $\delta = 1$.

V. The Chern band basis

In this section we show that, if the two bands $\epsilon_{-1}(k)$ and $\epsilon_1(k)$ are gapped from other bands, we can recombine them as two Chern bands with Chern numbers $e_2$ and $-e_2$, with $e_2$ being the Euler’s class [54, 132–134] (or, equivalently, the Wilson loop winding number protected by $C_2T$ [44]). (In TBG, the Chern numbers given by $\pm e_2$ are also equal to the $e_v = \pm 1$ index defined in Ref. [111], which, in a certain gauge, represents the eigenvalue of the Pauli $y$ matrix in the 2-dimensional space of $n = \pm 1$ band indices.)

In order to introduce the Chern band basis, we first introduce the definition of Euler’s class $e_2$. (We refer the readers to Refs. [54, 132, 44] for more details.) Suppose the two bands $\epsilon_1(k)$ and $\epsilon_{-1}(k)$ are gapped from other bands. Then, at $k$ away from Dirac points between the two bands, the $C_2T$ operator leaves each band unchanged up to a phase factor. In other words, the $C_2T$ sewing matrix (Eq. (20)) is diagonal at these $k$. Hence in general, the $C_2T$ symmetry acts on the Bloch states as $C_2T|u_n(k)⟩ = |u_n(k)⟩e^{i\theta_n(k)}$ ($n = \pm 1$), with $\theta_n(k)$ being the phase factors. According to Ref. [54], it follows that the non-Abelian Berry’s connection of the two bands at $k$ away from Dirac points takes the form

$$A_{nn'}(k) = i⟨u_n(k)|∂_k u_{n'}(k)⟩ = \left(\frac{1}{2\pi}\partial_k \theta_1(k) - i\partial_k \epsilon_1(k) \frac{\epsilon_1(k) - \epsilon_{-1}(k)}{2} \frac{1}{\partial_k \theta_1(k)}\right)_{nn'} (24)$$

$a(k)$ is a gauge invariant quantity up to a global ambiguity of $\pm$ sign. The Euler’s class is given by

$$e_2 = \frac{1}{2\pi} \int_{BZ} d^2k \cdot a(k) = \frac{1}{2\pi} \sum \langle \partial_{D_i} \cdot a(k) \rangle$$

Here $i$ indexes the Dirac points in the BZ, $D_i$ is a sufficiently small region covering the $i$-th Dirac point, $BZ' = BZ - \sum D_i$, and $f(k) = \partial_k \times a(k)$.

In the above we have assumed that $|u_n(k)⟩$ is smooth over the Brillouin zone except at the Dirac points. Eq. (24) is valid only in this gauge. In this gauge $\theta_n(k)$ is necessarily k-dependent if there exist Dirac points between the $n$th band and other bands. Since each Dirac point contributes to a $\pi$ Berry’s phase, there must be $2\pi$ mod $4\pi$. Thus $\theta_n(k)$ must wind odd times around a Dirac point. We introduce the two Chern band basis as

$$|v_{\pm}(k)⟩ = \frac{1}{\sqrt{2}}(e^{i\frac{\theta_1(k)}{2}}|u_1(k)⟩ \pm ie^{i\frac{\theta_{-1}(k)}{2}}|u_{-1}(k)⟩). \quad (26)$$

There are two ambiguities in the above equation: (i) There is an ambiguity of the two branches of $e_2$, i.e., $\frac{\theta_1}{2}$ and $\frac{\theta_{-1}}{2} + \pi$. (ii) At the Dirac points, where the two bands are degenerate, there is an ambiguity of choosing $u_1(k)$ and $u_{-1}(k)$. Replacing $\theta_1(k)/2$ by $\theta_1(k)/2 + \pi$ or replacing $\theta_{-1}(k)/2$ by $\theta_{-1}(k)/2 + \pi$ will interchange
\[ |v_+(k)\rangle \] with \[ |v_-(k)\rangle \]. Similarly, interchanging \[ |v_1(k)\rangle \] and \[ |v_{-1}(k)\rangle \] at the Dirac points will also interchange \[ |v_+(k)\rangle \] with \[ |v_-(k)\rangle \] at the Dirac points. To solve these ambiguities, as detailed in Appendix C, we require that the Berry’s curvatures of \[ |v_+(k)\rangle \] and \[ |v_-(k)\rangle \] to be continuous, or, equivalently,

\[ \lim_{|q|\to 0} |\langle v_{m}(k+q)|v_{m}(k)\rangle| = \delta_{m',m}, \tag{27} \]

where \( m, m' = \pm \). Using Eqs. (24) and (26), we can calculate the non-Abelian Berry’s connection on the basis \[ |v_\pm(k)\rangle \] at \( k \) away from the Dirac points. We obtain

\[ A'_{mm'}(k) = i\langle v_m(k)|\partial_k v_{m'}(k)\rangle = \left( \begin{array}{cc} a(k) & 0 \\ 0 & -a(k) \end{array} \right)_{mm'}, \tag{28} \]

and hence

\[ F_{mm'} = -[\partial_{k_x} - A'_{x}, \partial_{k_y} - A'_{y}]_{mm'} = \left( \begin{array}{cc} f(k) & 0 \\ 0 & -f(k) \end{array} \right)_{mm'}. \tag{29} \]

for \( k \) not at the Dirac points. Therefore, if the Berry’s curvature does not diverge at Dirac points, which is true as shown in next paragraph, the Chern numbers of the states \[ |v_\pm(k)\rangle \] are

\[ C_{\pm} = \pm \frac{1}{2\pi} \int d^2k \ f(k) = \pm e_2. \tag{30} \]

To conclude this section, we show that in the chiral limit \( \omega_0 = 0 \) the Chern band basis can be chosen as the eigenstates of the chiral symmetry \( C \) (Eq. (7)). We define the sewing matrix of \( C \) as

\[ C|u_n(k)\rangle = \sum_{n'} |u_{n'}(k)\rangle B^{(C)}_{n'n}(k), \tag{31} \]

where the summation over \( n' \) satisfies \( \epsilon_{n'}(k) = -\epsilon_n(k) \). For the TBG Hamiltonian Eq. (1), the \( C_2zT \) and \( C \) operators are \( \sigma_x K \) and \( \sigma_z \), respectively. Thus we have the algebra \( C^2 = 1 \) and \( \{ C, C_2zT \} = 0 \) and hence

\[ [B^{(C)}(k)]^2 = 1, \tag{32} \]

\[ B^{(C_2zT)}(k)B^{(C_2zT)}(k) + B^{(C)}(k)B^{(C_2zT)}(k) = 0. \tag{33} \]

As discussed at the beginning of this section, at \( k \) not at the Dirac points, we have \( B^{(C_2zT)}(k) = \delta_{n',n}e^{i\theta_n(k)} \). Then the solution of \( B^{(C)}(k) \) is

\[ B^{(C)}(k) = \pm \left( \begin{array}{cc} 0 & -i e^{i\theta_n(k) - \theta_{n'}(k)} \\ i e^{i\theta_n(k) - \theta_{n'}(k)} & 0 \end{array} \right). \tag{34} \]

The \( \pm \) sign cannot be determined by solving Eqs. (32) and (33). In practice, one should evaluate Eq. (31) to determine the \( \pm \) sign for given \( |u_{\pm 1}(k)\rangle \). We find that the Chern band basis Eq. (26) diagonalizes \( B^{(C)}(k) \). Below Eq. (26) we have discussed the ambiguity of choosing \( |v_\pm(k)\rangle \) and we have imposed Eq. (27) to fix this ambiguity. This ambiguity of Eq. (26) can be alternatively solved by choosing \( |v_\pm(k)\rangle \) as the eigenstates of \( C \) with the eigenvalues \( \pm 1 \), respectively. This choice automatically satisfies Eq. (27) since the states with different chiral eigenvalues are orthogonal, i.e., \( \langle v_-(k)|v_+(k')\rangle = \langle v_-(k)|C|v_+(k')\rangle = -\langle v_-(k)|v_+(k')\rangle = 0 \) for arbitrary \( k \) and \( k' \).

The Chern band basis in Eq. (26) can also be equivalently defined through the Wilson loop method [29, 86]. Besides, in the chiral limit, the Chern band basis we defined is equivalent to that defined in [19].
FIG. 6. Perfect metal phase of twisted bilayer graphene in the second chiral limit \((w_1 = 0)\). (a) The band structure at \(\theta = 1.05^\circ\) with the parameters \(v_F = 5.94\) eV \(\cdot\) Å, \(|K| = 1.703\) Å\(^{-1}\), \(w_1 = 0\), \(w_0 = 77\) meV. (b) The Brillouin zone of the twisted bilayer graphene. The solid black lines represent the \(C_{2z}\)-axis and its conjugations under \(C_{3z}\), the dashed black lines represent the effective mirror symmetry \(M_z = C_{2z}I\) and its conjugations under \(C_{3z}\). The red dots represent Dirac points in the mirror lines. The blue dots represent Dirac points at generic momenta.

VI. Perfect metal phase of twisted bilayer graphene in the second chiral limit

In our article Ref. [111], we consider the opposite limit of the usual chiral limit: Instead of letting \(w_0 = 0\), we take \(w_1 = 0\) to be zero. When \(w_1 = 0\), the model Eq. (1) has another chiral symmetry \(C' = \tau_z\sigma_z\) acting on the Hamiltonian as \(C' = H(r)C' = -H(r)\). Thus we call this limit as the second chiral limit. As discussed in Section II A, \(w_0\) and \(w_1\) are the interlayer couplings contributed mainly by the AA and AB/BA regions, respectively; thus the second chiral limit can be (approximately) realized if the layer distance in the AA region is smaller than the layer distance in the AB and BA regions (shorter distance means stronger coupling). Such a configuration would be different from the corrugation predicted by the first principle calculations [120–123], where the distance in the AA region is larger. Nevertheless, the second chiral limit might could potentially be engineered by putting the TBG on certain substrate, and it represents an interesting interacting limit [111]. We are mainly interested in the novel electronic band structure of TBG in the second chiral limit and hence we leave the material realization of the second chiral limit for future study.

We find that, in the second chiral limit, the \(n\)-th positive (negative) band is always connected to the \((n+1)\)-th positive (negative) band. As the first positive band and the first negative band are connected through the Dirac points, the whole bands are all connected, as shown in Fig. 6a. The phase with all bands connected is referred to as the perfect metal [135] in trilayer systems, where the number of Dirac nodes is odd. In the current case, we also find this “perfect metal” in even number of Dirac node systems with the special chiral symmetry of the second chiral limit.

The perfect metal phase is protected by \(C_{2z}T\), \(P\), and \(C'\). The new chiral symmetry \(C'\) has a strange group algebra as it anticommutes with \(T\) and with \(P\) [112]. We define the product of \(P\) and \(C'\) as an effective inversion symmetry \(I = PC' = \tau_z\sigma_z\). It commutes with the Hamiltonian, i.e., \(H(-r) = IH(r)I^\dagger\) and \(H(-k) = IH(k)I^\dagger\) accordingly. The effective inversion operator satisfies the algebra

\[
\{C_{2z}T, I\} = 0, \quad \{P, I\} = 0, \quad I^2 = 1. \quad (35)
\]

We first show that \(C_{2z}T\) and \(I\) protect double degeneracies at \(I\)-invariant momenta. (In TBG, the \(I\)-invariant momenta are \(\Gamma_M\) and the three equivalent \(M_M\).) Since the Hamiltonian at an \(I\)-invariant momentum commutes with \(I\), the Bloch states at this momentum must form eigenstates of \(I\). Suppose \(|u\rangle\) is such an eigenstate with \(I = 1\), then we can show that \(C_{2z}T|u\rangle\) must have the opposite \(I = -1\) due to the anti-commutation between \(C_{2z}T\) and \(I\). Therefore \(|u\rangle\) and \(C_{2z}T|u\rangle\) form a doublet that has opposite \(I\) eigenvalues. This explains the double degeneracies at \(\Gamma_M\) and \(M_M\) shown in Fig. 6a.

Next we prove that, for arbitrary even \(M\), the \(M\)-th positive band is connected to the \((M + 1)\)-th positive bands through \(4l + 2\) \((l \in \mathbb{N})\) Dirac points. (For odd \(M\), we know by counting - see Fig. 6 - that the \(M\)-th band is connected to the \((M + 1)\)-th band through the double degeneracies at the \(I\)-invariant momenta.)

We only need to prove for the situation where the four bands \(\epsilon_{M-1}(k), \epsilon_M(k), \epsilon_{M+1}(k), \epsilon_{M+2}(k)\) do not form four-fold degeneracies at high symmetry momenta since otherwise \(\epsilon_M(k)\) is already connected to \(\epsilon_{M+1}(k)\). As shown in Fig. 6a, we also do not observe four-fold degeneracies at high symmetry momenta.) We assume there are in total \(n_D\) Dirac points between the first \(M\) positive bands \(\epsilon_1(k) \cdots \epsilon_M(k)\) and the other bands. The \(n_D\) Dirac points can appear above the \(M\)-th band, i.e., between \(\epsilon_M(k)\) and \(\epsilon_{M+1}(k)\), or below the first band, i.e., between \(\epsilon_1(k)\) and \(\epsilon_{-1}(k)\). According to the \(I\) symmetry, half of the BZ (\(B\)) must have \(n_D/2\) Dirac points. (The choice of \(B\) is not unique. An example is shown in Fig. 4.) With the \(C_{2z}T\) symmetry, the number of Dirac points in \(B\) is related to the Berry’s phase surrounding \(B\) as [131]

\[
\frac{n_D}{2} = \frac{1}{\pi} \int_{\partial B} d\mathbf{k} \cdot \mathbf{A}(\mathbf{k}) \mod 2, \quad (36)
\]

where \(\mathbf{A}(\mathbf{k}) = \sum_{n=1}^{M} i \langle u_n(k) | \partial_k u_n(k) \rangle\) is the Berry’s connection of the first \(M\) positive bands. In presence of the effective inversion symmetry \(I\), the right hand side of the above equation is determined by the \(I\) eigenvalues as [128, 136–138]

\[
\exp \left( i \int_{\partial B} d\mathbf{k} \cdot \mathbf{A}(\mathbf{k}) \right) = \prod_{K} \prod_{n=1}^{M} \xi_{K,n}, \quad (37)
\]

where \(K\) indexes the four \(I\)-invariant momenta, and \(\xi_{K,n}\) is the \(I\) eigenvalue of the \(n\)-th positive band at the momentum \(K\). As discussed in the last paragraph, each doublet at an \(I\)-invariant momentum has opposite \(I\) eigenvalues. Thus, there are equal number of \(I\) eigenvalues...
1 and −1 at the $I$-invariant momenta; since the total number of states at the four $I$-invariant momenta is $4M$, there are $2M$ eigenvalues with $I = +1$ and $2M$ eigenvalues with $I = −1$. Hence the right hand side of Eq. (37) is 1 and we have $\oint_{\text{TBG}} d\mathbf{k} \cdot \mathbf{A}'(\mathbf{k}) = 0 \mod 2\pi$. According to Eq. (36), the total number of Dirac points is a multiple of 4, i.e., $n_D = 0 \mod 4$. As we have proved in Section IV, there must be $4l' + 2$ ($l' \in \mathbb{N}$) Dirac points between $\epsilon_1(\mathbf{k})$ and $\epsilon_{−1}(\mathbf{k})$, then the number of Dirac points between $\epsilon_M(\mathbf{k})$ and $\epsilon_{M+1}(\mathbf{k})$ is $n_D = 4l' − 2 = 4l + 2$ with $l = n_D/4 − l' − 1 \in \mathbb{N}$. Thus the $M$-th positive band is always connected to the $(M+1)$-th positive band through $4l + 2$ Dirac points. According to the particle-hole symmetry $P$, the $M$-th negative band is also connected to the $(M+1)$-th negative band through $4l + 2$ Dirac points. Therefore, the whole set of bands in the system will be connected.

In general, the $4l + 2$ Dirac points between the $M$-th band the $(M+1)$-th band can be located anywhere in the BZ. However, with the $C_{3z}$ and the $C_{2x}$ symmetries of TBG, at least some of the $4l + 2$ Dirac points must locate at high symmetry point or along high symmetry lines of the BZ. We prove this statement by contradiction. The unitary point group of TBG is generated by $C_{3z}, C_{2x}$, and the effective inversion $I$ and hence is isomorphic to the point group $D_{3h}$, which has 12 elements in total. If all the Dirac points between the $M$-th band the $(M+1)$-th band are located at generic momenta, then the number of Dirac points would be a multiple of 12, as represented by the blue dots in Fig. 6b, leading to a contradictory with the $4l + 2$ Dirac points. Therefore, there must be 2 (modulo 4) Dirac points at the high symmetry points or along the high symmetry lines. As a consequence, the entire set of bands of TBG in the second chiral limit must be connected along the high symmetry lines. For example, as shown in Fig. 6a, there is a crossing between the 2nd and 3rd bands in the high symmetry line $T_M − K_M$. (This crossing is protected by the effective mirror symmetry $M_L = C_{2x}I$.) Under the actions of $C_{2x}$ and $C_{3z}$, there are in total six symmetry counterparts of this crossing point (including itself). Thus the number of Dirac points is consistent with $4l + 2$ with $l = 1$.

VII. Conclusions

In this work, we showed that even the simple, well-studied BM TBG model still has several surprises related to the deep physics that it describes. We have proved that the band structure in a single graphene valley of TBG is anomalous, i.e., does not have lattice support that respects the $C_{2x}T$ and $P$ symmetries. The anomaly manifests as (i) a $\mathbb{Z}_2$ nontrivial topology protected $P$ of the $2M$ bands $-\epsilon_M(\mathbf{k}) \cdots \epsilon_M(\mathbf{k})$ for arbitrary $M$, provided that the $2M$ bands are gapped from other bands, (ii) $4l + 2$ $(l \in \mathbb{N})$ Dirac points between $\epsilon_{−1}(\mathbf{k})$ and $\epsilon_1(\mathbf{k})$. In the second chiral limit $(w_1 = 0)$, the anomaly manifests as (iii) a perfect metal phase where all the bands are connected.

As a consequence of the symmetry anomaly, a faithful description of TBG that respects all the symmetries of TBG, including $P$, is forced to adopt a momentum space formalism. Any tight-binding description [19, 52, 53, 55, 65] of TBG with finite number of orbitals must break at least one of the $C_{2x}T$ and $P$ symmetries (or the valley symmetry if the tight-binding model mix the two graphene valleys of TBG). In the other works of our series on TBG [110–114], the interacting physics is studied using a momentum space formalism.

A. Hamiltonian of twisted bilayer graphene in momentum space

1. The Hamiltonian

Here we briefly introduce the momentum space Hamiltonian $H(k)$ corresponding to Eq. (1). Readers may refer to the supplementary materials of Ref. [56] for more details. The basis of $H(k)$ is $|\phi_{Q,\alpha}(k)\rangle$, where $k$ is a momentum in the moiré BZ, $Q$ is a point in the lattice shown in Fig. 7, and $\alpha = 1, 2$ is the sublattice index of graphene. There are two types of lattices of the bottom layer graphene, $N$ is the number of lattices in the bottom layer graphene, $|R\rangle$ is the atomic orbital of $R$, and $|t\rangle$ is the sublattice index of $t$. The Hamiltonian (Eq. (1)) on the basis $|\phi_{Q,\alpha}(k)\rangle$ is given by

$$H_{Q,\alpha}(k) = \frac{1}{\sqrt{N}} \sum_{R,T} e^{i(k+R+Q)\cdot R} |R\rangle \cdot |R\rangle + \frac{3}{2} \zeta_{Q} \delta_{Q,Q'} (k-Q) \times$$

$$+ \sum_{j=1}^{3} (\delta_{Q'-Q,\alpha} + \delta_{Q-Q',\alpha}) T_{j},$$

where $\sigma = (\sigma_{x}, \sigma_{y})$ and $T_{j}$ $(j = 1, 2, 3)$ are two-by-two matrices in the sublattice space, $\zeta_{Q} = 1$ for $Q \in Q_{T}$ and $\zeta_{Q} = -1$ for $Q \in Q_{B}$.

2. The periodicity of Bloch states

An eigenstate of Eq. (1) at a given momentum $k$ can be written as linear combination of the Bloch basis $|\psi_{n}(k)\rangle = \sum_{Q,\alpha} |\phi_{Q,\alpha}(k)\rangle u_{Q,\alpha,n}(k)$. Here $n$ is the band index. It should be noticed that the basis states in Eqs. (A1) and (A2) are not periodic in the moiré BZ since $|\phi_{Q,\alpha}(k+G)\rangle = |\phi_{Q,\alpha}(k)\rangle$ by definition. In order for the Bloch state $|\psi_{n}(k)\rangle$ to be periodic in the moiré BZ, i.e., $|\psi_{n}(k+G)\rangle = |\psi_{n}(k)\rangle$, $u_{Q,\alpha}(k)$ should satisfy $u_{Q,\alpha}(k+G) = u_{Q-G,\alpha}(k)$. We introduce the embedding matrix

$$V_{Q,Q'}^{G} = \delta_{Q-Q',G} = \delta_{Q-G',Q},$$

such that we can write the periodicity of Bloch states as

$$|u_{n}(k+G)\rangle = V_{G}^{Q} |u_{n}(k)\rangle,$$

where $|u_{n}(k)\rangle = (u_{Q_{1},1,n}(k), u_{Q_{1},2,n}(k), u_{Q_{2},1,n}(k), \ldots)^{T}$. While exact Bloch periodicity requires that the cutoff in the lattice $Q$ be large, we have showed - around the first magic angle - [110] that we can obtain machine precision accuracy in the first moiré BZ by taking a small cutoff in $Q$.

3. Symmetry operators in the momentum space

The crystalline symmetry group of the single valley Hamiltonian is the magnetic space group $P\overline{6}m2'$ (#177,151 in the BNS setting [124]). The generators of this group are: The $C_{3z}$ symmetry

$$H(C_{3z}k) = D(C_{3z}) H(C_{3z}k) D^{\dagger}(C_{3z})$$

where $D_{Q',Q}(C_{3z}) = e^{i\frac{2\pi}{3} \sigma_{z} \delta_{Q',C_{3z},Q}}$. The $C_{2x}$ symmetry

$$H(C_{2x}k) = D(C_{2x}) H(C_{2x}k) D^{\dagger}(C_{2x})$$

where $D_{Q',Q}(C_{2x}) = \sigma_{x} \delta_{Q',C_{2x},Q}$, and $C_{2x}q_{1} = -q_{1}$. The $C_{2z}$ symmetry

$$H(k) = D(C_{2z}) H_{Q,Q'}(k) D^{T}(C_{2z})$$

where $D_{Q,Q'}(C_{2z}) = \sigma_{y} \delta_{Q',Q}$. It should be noticed that all rotations of momenta here are with respect to the $\Gamma_{M}$ point of the moiré BZ. When the second term in Eq. (A3) is negligible, $H(k)$ has an emergent unitary particle-hole symmetry

$$H(-k) = -D(P) H(k) D^{\dagger}(P).$$
where \( D_{Q',Q}(P) = \delta_{Q',Q} \), and \( \zeta_Q = 1 \) for \( Q \in Q_x \) and \( \zeta_Q = -1 \) for \( Q \in Q_y \). The anti-unitary particle-hole symmetry \( \mathcal{P} = P \mathcal{C}_{2z} T \) in momentum space is

\[
H(-k) = -D(P)H^*(-k)D^T(P),
\]

(A10)

where \( D_{Q,Q'}(P) = \sigma_z \delta_{Q,Q'} \). When \( \omega_0 = 0 \), \( H(k) \) has an emergent chiral symmetry

\[
H(k) = -D^\dagger(C)H(k)D(C),
\]

(A11)

where \( D_{Q,Q'}(C) = \sigma_z \delta_{Q,Q'} \).

Using the identities Eqs. (A13) and (A14), we obtain that

\[
E_{\mathcal{P}} = \sum_{G} s_G e^{iG\mathbf{r}}.
\]

(B2)

\( s_G \) is an odd function of \( \mathbf{G} \) and is dominated by the components on the shortest \( \mathbf{G} \) vectors \([140]\). For example, for \( |\mathbf{G}| = |b_M| \), \( s_G \) takes the form \([140]\)

\[
s_G = \frac{s_0}{|b_M|}(G_y,G_x), \quad (|\mathbf{G}| = |b_M|),
\]

(B3)

where \( s_0 \) is the length of the displacement vectors. The in-plane displacement leads to two new terms in the Hamiltonian of TBG: (i) the correction of the intralayer hopping, which has a form of pseudo vector potential, (ii) the correction to the interlayer hopping. The pseudo vector potential has the form \( \mathbf{A} \)

\[
\mathbf{A}_x(r) = \gamma[s_{xx}(r) - s_{yx}(r)], \quad \mathbf{A}_y(r) = -2\gamma s_{xy}(r)
\]

(B4)

with \( s_{ij} = \frac{1}{2}(\partial_i v_j + \partial_j v_i) \) being the strain tensor and \( \gamma \) the coupling constant. Since \( s_G \) is real and odd in \( \mathbf{G} \), \( \mathbf{A}(r) \) is real and even in \( r \). The pseudo vector potential enters the TBG Hamiltonian as

\[
-iv_F \partial_s \cdot \sigma \rightarrow v_F (-i\partial_s + A(r)\tau_z) \cdot \sigma.
\]

(B5)

The \( \tau_z \) factor in the pseudo vector potential term comes from the fact \( s^{(T)} = -s^{(B)} = s(r) \) (Eq. (B1)). We find that the pseudo vector potential term respects all the symmetries. In particular, it respects the \( \mathcal{C}_{2z} T = \sigma_z K \) and the \( \mathcal{P} = i\tau_y \sigma_x K \) symmetries, which protect the stable topology.

With the in-plane displacement fields, the interlayer coupling changes to \([140]\)

\[
T(r) \rightarrow \tilde{T}(r) = \sum_{i=1}^3 e^{-i\mathbf{K}_i \cdot \mathbf{r}} \cdot T_i,
\]

(B6)

where \( \mathbf{K}_1 \) is the \( \mathbf{K} \) vector shown in Fig. 7, \( \mathbf{K}_2 = \mathbf{C}_3z \mathbf{K}_1 \), \( \mathbf{K}_3 = \mathbf{C}_3z \mathbf{K}_2 \), and \( T_i \) are given in Eq. (3). The corresponding Hamiltonian matrix can be written as

\[
\begin{pmatrix}
0 & \tilde{T}(r) \\
\tilde{T}^\dagger(r) & 0
\end{pmatrix}
= \sum_{i} (f_i(r)\tau_x \otimes T_i + g_i(r)\tau_y \otimes T_i),
\]

(B7)

with \( f_i(r) \) and \( g_i(r) \) being the real part and imaginary part of \( e^{-i\mathbf{K}_i \cdot \mathbf{r}} \), respectively. Since \( s(r) \) is odd in \( r \), there is \( f_i(r) = f_i(-r) \) and \( g_i(r) = -g_i(r) \). One can find that the interlayer coupling respects both \( \mathcal{C}_{2z} T = \sigma_x K \) and \( \mathcal{P} = i\tau_y \sigma_x K \).

Therefore, the in-plane relaxation does not directly lead to particle-hole symmetry breaking. This is also numerically shown in Refs. [140] and [141].
2. \textbf{k-dependence in the interlayer hopping}

The continuous models of TBG discussed in the rest of this work have made an approximation on the interlayer coupling: We have neglected the \textbf{k}-dependence of the Fourier transformation of the interlayer hopping. Refs. [140] and [141] have shown that keeping the \textbf{k}-dependence in \( f(\textbf{q}) \) will lead to a particle-hole asymmetry in the energy spectrum. Ref. [141] shows that keeping linear order of \( \textbf{k} \) in the \textbf{k}-dependence is a good approximation. Here we derive the linear \textbf{k}-dependence explicitly. Following Eq. (14) of the supplementary material of Ref. [56], we have the intervalley coupling on the basis Eqs. (A1) and (A2)

\[
H_{Q,Q'}(\textbf{k}) = \sum_{j=1}^{3} t_{K_j + \textbf{k} - Q} \delta_{Q,Q'} \cdot \hat{T}_j \quad (Q \in Q_T, Q' \in Q_B) \tag{B8}
\]

where \( t_{\textbf{q}} = t_0 \exp(-\alpha(|\textbf{q}|d_{\perp})\gamma) \) is the Fourier transformation of the interlayer coupling with \( d_{\perp} \) being the distance between the two layers, and

\[
\hat{T}_i = \sigma_0 + \left[ \sigma_x \cos \frac{2\pi(i-1)}{3} + \sigma_y \sin \frac{2\pi(i-1)}{3} \right]. \tag{B9}
\]

Here \( \textbf{K}_1 \) is the \( \textbf{K} \) vector shown in Fig. 7, \( \textbf{K}_2 = C_{3z} \textbf{K}_1, \textbf{K}_3 = C_{3z} \textbf{K}_2 \). The parameters in \( t_{\textbf{q}} \) have been fitted as \( \alpha = 0.13, \gamma = 1.25 \). For simplicity here we assume \( d_{\perp} \) is uniform in real space.

We expand \( t_{\textbf{k}_j + \textbf{k} - Q} \) to leading order of \( \textbf{k} - Q \) as

\[
t_{\textbf{k}_j + \textbf{k} - Q} \approx t_{\textbf{K}_j} \left( 1 - \alpha \gamma (d_{\perp} |\textbf{K}_j|)^\gamma \frac{\textbf{K}_j \cdot (\textbf{k} - Q)}{|\textbf{K}_j|^2} \right) \tag{B10}
\]

Then we obtain the correction to the continuous model as

\[
\delta H_{Q,Q'}(\textbf{k}) = -\lambda \sum_{j=1}^{3} \delta_{Q,Q' - q_j} \cdot \frac{\textbf{K}_j \cdot (\textbf{k} - Q)}{|\textbf{K}_j|^2} \cdot \hat{T}_j \tag{B11}
\]

for \( Q \in Q_T, Q' \in Q_B \), and

\[
\delta H_{Q,Q'}(\textbf{k}) = -\lambda \sum_{j=1}^{3} \delta_{Q,Q' + q_j} \cdot \frac{\textbf{K}_j \cdot (\textbf{k} - Q')}{|\textbf{K}_j|^2} \cdot \hat{T}_j \tag{B12}
\]

for \( Q \in Q_B, Q' \in Q_T \). Here \( \lambda = t_{\textbf{K}} \alpha \gamma (d_{\perp} |\textbf{K}|)^\gamma \). Since \( \delta H_{Q,Q'}(\textbf{k}) \) still consists of \( \sigma_0, \sigma_x, \sigma_y \), it respects the \( C_{2z}T \) symmetry. However, it breaks the unitary particle-hole symmetry \( P \) (Eq. (4)) and hence the anti-unitary particle-hole symmetry \( \mathcal{P} = P \cdot C_{2z}T \). We use the parameter \( \lambda = 180\text{meV} \) to make a significant particle-hole asymmetry in the band structure: the lower band at \( \Gamma_M \) has the energy \(-1.34\text{meV} \) and the upper band has the energy \(5.16\text{meV} \) (Fig. 8). However, we find that the error of the particle-hole symmetry for the Bloch wavefunctions (Eq. (9)) as \( \exp(\mathcal{P}) = 0.07 \), which is still weak. A more realistic model should include both the in-plane relaxation and the \textbf{k}-dependence of the interlayer hopping [140, 141]. As discussed in the last subsection, without the \textbf{k}-dependence, the in-plane relaxation will not lead to \( \mathcal{P} \)-breaking. Hence we claim that the error of the \( \mathcal{P} \) symmetry in this more realistic model will have the same order as 0.13.

C. \textbf{The gauge of Chern band basis}

In Section V we have explained that the choice of Chern band basis due to the \( C_{2z}T \) gauge fixing (Eq. (26)) has two ambiguities: (i) the choice of the two branches of \( \frac{\theta_0(\textbf{k})}{2}, \) i.e., \( \frac{\theta_0(\textbf{k})}{2} + \pi \), and (ii) the choice of \( |u_1(\textbf{k})\rangle \) and \( |u_{-1}(\textbf{k})\rangle \) at Dirac points where the two bands are degenerate. Both ambiguities lead to an ambiguity when choosing \( |v_\pm(\textbf{k})\rangle \). If we replace \( \frac{\theta_1(\textbf{k})}{2} \) by \( \frac{\theta_1(\textbf{k})}{2} + \pi \) in Eq. (26), then the two Chern band states in the new gauge \( |v'_\pm(\textbf{k})\rangle \) are related to the Chern band states in the previous gauge as

\[
|v'_\pm(\textbf{k})\rangle = \frac{1}{\sqrt{2}} (\mp e^{i \frac{\theta_1(k)}{2}} |u_1(\textbf{k})\rangle \pm ie^{i \frac{\theta_1(k)}{2}} |u_{-1}(\textbf{k})\rangle) = \pm |v_\mp(\textbf{k})\rangle. \tag{C1}
\]

Therefore, changing the branch of \( \frac{\theta_1(\textbf{k})}{2} \) at \( \textbf{k} \) will interchange the two states \( |v_\pm(\textbf{k})\rangle \) at \( \textbf{k} \). One can show that changing the branch of \( \frac{\theta_{-1}(\textbf{k})}{2} \) will also interchange the two states \( |v_\pm(\textbf{k})\rangle \) for the same reason. We then consider to interchange \( |u_{\pm 1}(\textbf{k}_D)\rangle \) at a Dirac point \( \textbf{k}_D \).

The Chern band states \( |v'_\pm(\textbf{k}_D)\rangle \) defined with the interchanged \( |u_{\pm 1}(\textbf{k}_D)\rangle \) become

\[
|v'_\pm(\textbf{k}_D)\rangle = \frac{1}{\sqrt{2}} (e^{i \frac{\theta_{-1}(\textbf{k}_D)}{2}} |u_{-1}(\textbf{k}_D)\rangle \pm ie^{i \frac{\theta_{-1}(\textbf{k}_D)}{2}} |u_1(\textbf{k}_D)\rangle) = \pm i |v_\mp(\textbf{k}_D)\rangle. \tag{C2}
\]
Thus interchanging $|u_{\pm 1}(k)\rangle$ at Dirac points will inter-
change $|v_{\pm}(k)\rangle$ at the Dirac points.

Due to the ambiguities discussed above, at each $k$ point
we only have two choices for $|v_{\pm}(k)\rangle$ (up to phase
factors). Starting with $|v_{\pm}(k_0)\rangle$ at a given momentum $k_0$,
the condition Eq. (27) will uniquely determine the two
branches of $|v_{\pm}(k)\rangle$ over the whole BZ. To be specific, we
consider the choice of $|v_{\pm}(k_0 + q)\rangle$ for $q$ being a small
momentum. Suppose $|v'_{\pm}(k_0 + q)\rangle$ is returned by Eq. (26)
without considering Eq. (27). Then if they satisfy
$|(v_{m}(k_0)|v'_{m'}(k_0 + q))\rangle \approx \delta_{mm'}$, we choose $|v_{\pm}(k_0 + q)\rangle =
|v'_{\pm}(k_0 + q)\rangle$; otherwise, i.e., $|(v_{m}(k_0)|v'_{m'}(k_0 + q))\rangle \approx
1 - \delta_{mm'}$, we choose $|v_{\pm}(k_0 + q)\rangle = |v'_{\pm}(k_0 + q)\rangle$. Re-
peating this procedure over the whole BZ iteratively will
uniquely determined the two branches of $|v_{\pm}(k)\rangle$.

We now explain why the obtained two branches by the
method introduced above must be Chern bands. We first
consider $k$ not at the Dirac points. Due to the discus-
sion in Section V, if a smooth branch of $\theta_{2}(k)$ is chosen,
the states $|v_{\pm}(k)\rangle$ will have smooth Berry’s curvatures
\(\pm f(k)\). On the other hand, if the branch of $\theta_{2}(k)$
changes at $k_*$, then there is
$\lim_{q\to 0} |\langle v_+(k_*)|v_+(k_* + q)\rangle| =
|\langle v_-(k_*)|v_-(k_*)\rangle| = 0$ and hence the Berry’s curvatures
of $|v_{\pm}(k)\rangle$ will be discontinuous at $k_*$. Therefore,
choosing a smooth branch of $\theta_{2}(k)$ is equivalent to choos-
ing $|v_{\pm}(k)\rangle$ such that they have continuous Berry’s curvatures.
Thus Eq. (27), which guarantees continuous
Berry’s curvatures, also enforces that $|v_{\pm}(k)\rangle$ must have the
Berry’s curvatures $\pm f(k)$. We then consider the
Dirac points. Since there is a finite number of Dirac
points in the BZ, the integral of Berry’s curvature in the
(infinite small) neighborhoods of the Dirac points
approaches zero as long as Eq. (27) holds such that the
Berry’s curvature is non-divergent. Therefore, the inte-
gral of Berry’s curvatures of $|v_{\pm}(k)\rangle$ subject to the con-
dition Eq. (27) are $\pm \frac{1}{\pi} \int d^2 k f(k) = \pm \epsilon_2$.

Now we explicitly show why the Berry’s curvatures of
Eq. (26) are not divergent at the Dirac points if Eq. (27)
holds. We consider a linearized k-p model around a single
Dirac point $H = k_x \sigma_x + k_y \sigma_y$, where the $C_{2z}T$
operator is $\sigma_z K$. Since Berry’s curvature is gauge-invariant, we
take the particular gauge $\theta_1(k) = \theta_{-1}(k) = 0$ in the
calculation. The Bloch states in this gauge are

$$
|u_1(k)\rangle = \frac{1}{\sqrt{2}} \left( e^{-i \frac{\phi(k)}{2}} \ e^{i \frac{\phi(k)}{2}} \right),
|u_{-1}(k)\rangle = \frac{1}{\sqrt{2}} \left( -ie^{-i \frac{\phi(k)}{2}} \ e^{i \frac{\phi(k)}{2}} \right),
$$

where $\phi(k) = \arccos \frac{k_y}{\sqrt{k_x^2 + k_y^2}}$. Then the recombined
Chern basis are $|v_+(k)\rangle = (e^{-i \frac{\phi(k)}{2}}, 0)^T$, $|v_-(k)\rangle =
(0, e^{i \frac{\phi(k)}{2}})^T$. They satisfy Eq. (27) and have vanishing
Berry’s curvatures in the neighbourhood of the Dirac
point.
