(Dated: today)

We describe the decoherence process induced on a two-level quantum system in direct interaction with a non-equilibrium environment. The non-equilibrium feature is represented by a non-stationary random function corresponding to the fluctuating transition frequency between two quantum states coupled to the surroundings. In this framework, we compute the decoherence factors which have a characteristic “dip” related to the initial phases of the bath modes. We therefore study different types of environments, namely ohmic and supra-ohmic. These environments present different decoherence time-scales than the thermal environment we used to study. As a consequence, we compute analytically and numerically the non-unitary geometric phase for the qubit in a quasi-cyclic evolution under the presence of these particular non-equilibrium environments. We show in which cases decoherence effects could, in principle, be controlled in order to perform a measurement of the geometric phase using standard procedures.

I. INTRODUCTION

The spin-boson model is studied in a variety of fields, such as condensed matter physics, quantum optics, physical chemistry and quantum information science [1] in order to describe non-unitary effects induced in quantum systems due to a coupling with an external environment. For a quantum system, the influence of the surroundings plays a role at a fundamental level. When the environment is taken into consideration, the system dynamics can no longer be described in terms of pure quantum states and unitary evolution. From a practical point of view, all real systems interact with an environment to a greater or lesser extent, which means that we expect their quantum evolution to be plagued by non-unitary effects, namely dissipation and decoherence.

Most theoretical investigations of how the system is affected by the presence of an environment have been done using a thermal reservoir, usually assuming Markovian statistical properties and defined bath correlations [2, 3] (there are also works on non-Markovian models as, just for example, [4]). However, there has been some growing interest in modelling more realistic environments, sometimes called “composite” environments [5, 6]. In fact, the are many situations where the environment is better modelled by a non-equilibrium bath. Quantum dynamics in non-equilibrium environments has been previously considered by some recent investigations. For example, light-induced ultra-fast coherent electronic processes in chemical or biological systems may occur on sufficiently short time scales [8]. In these cases, initial non-equilibrium states induced in the bath through the coupling among system and environment, might not have the chance to reach equilibrium rapidly. Then, the transient non-equilibrium bath dynamics may undergo a non-trivial interaction with the system of interest in comparable time scales. Gordon et al discussed the control of quantum coherence and the suppression of dephasing by stochastic control fields [9]. In [9], the decoherence process induced by a non-equilibrium environment described by several equilibrium baths at different temperatures, is discussed. Therein, it was suggested that the effect of such environment on the quantum system could be described as the effect done by a single effective bath with a time-dependent temperature. The decoherence of single trapped ions coupled to engineered reservoirs, where the internal state and coupling can be controlled was studied in [10].

In this context, we shall describe a simple model which gives a different insight into the behaviour of a quantum system coupled to an environment that is not at thermal equilibrium. Herein, we study the dynamics of quantum coherence in non-equilibrium. We consider a two level quantum system in a non-equilibrium bath, represented by random perturbations with non-stationary statistics. Therefore, we shall study how the quantum system is affected by the decoherence induced by the environment. We shall compare this decoherence process with the usual results for a thermal environment.

From another point of view, a system can retain the information of its motion when it undergoes a cyclic evolution in the form of a geometric phase (GP), which was first put forward by Pancharatman in optics [11] and later studied explicitly by Berry in a general quantal system [12]. Since then, great progress has been achieved in this field. As an important evolvement, the application of the geometric phase has been proposed in many fields, such as the geometric quantum computation. Due to its global properties, the geometric phase is propitious to construct fault tolerant quantum gates. In this line of work, many physical systems have been investigated to realize geometric quantum computation, such as NMR (Nuclear Magnetic Resonance) [13], Josephson junction [14], Ion trap [15] and semiconductor quantum dots [16]. The quantum computation scheme for the GP has been proposed based on the Abelian or non-Abelian geomet-
ric concepts, and the GP has been shown to be robust against faults in the presence of some kind of external noise due to the geometric nature of Berry phase [17–19]. It was therefore seen that the interactions play an important role for the realization of some specific operations. As the gates operate slowly compared to the dynamical time scale, they become vulnerable to open system effects and parameters fluctuations that may lead to a loss of coherence. Consequently, study of the GP was soon extended to open quantum systems. Following this idea, many authors have analysed the correction to the GP under the influence of an external thermal environment using different approaches (see [20–23] and references therein).

In this paper, we shall study how the GP is affected by the presence of a non-equilibrium environment. We shall consider a two-state quantum system coupled to such an environment and derive the corresponding decoherence factor in Sec. III. We shall analyse the decoherence process for ohmic and non-ohmic environments. In Sec. III, we shall derive the GP for a non-unitary evolution of the quantum system in the presence of a non-equilibrium environment and compute how the GP is corrected in each case. Finally, in Sec. IV, we shall make our final remarks.

II. PURELY DEPHASING SOLVABLE SPIN-BOSON MODEL

A paradigmatic model of open quantum systems is a two-state quantum system coupled to a thermal environment. This is a particular case of the spin-boson model by A. Leggett [1] (where the tunnelling bare matrix element is $\Delta = 0$) and has been used by many authors to model decoherence in quantum computers [24] and, in particular, it is extremely relevant to the proposal for observing GPs in a superconducting nano-circuit [25]. In spite of its simplicity, this model captures many of the elements of decoherence theories and sheds some insight into the modification of the GPs due to the presence of the environment. The interaction between the two-state system and the environment is entirely represented by a Hamiltonian in which the coupling is only through $\sigma_z$.

In this particular case, $[\sigma_z, H_{\text{int}}] = 0$ and the corresponding master equation for the reduced density matrix, is much simplified, with no frequency renormalization and dissipation effects. In other words, the model describes a purely decohering (dephasing) mechanism, solely containing the diffusion term $D(t)$ [21]. In such a case, it is easy to check that

$$\rho_{\text{tot}}(t) = e^{-i\Omega t} e^{-\mathcal{A}(t)} \rho_{\text{tot}}(0),$$

is the solution for the off-diagonal terms of the reduced density matrix (while populations remain constant) and $\mathcal{A} = \int_0^\infty ds D(s)$. $\Omega$ refers to the angular frequency of precession of a spin precessing the $z$ axis as ruled by the isolated from the environment Hamiltonian $H_0 = \frac{1}{2}\Omega \sigma_z$ (responsible for the unitary evolution). The spin-boson model is the one used in Ref. [21] in order to present a solvable model to study how the GPs are corrected by decoherence in open systems. In that framework, we have studied not only how the GPs are corrected by the presence of the different type of environments but estimated the corresponding times at which decoherence becomes effective as well. These estimations should be taken into account when planning experimental setups, as the one performed in Ref. [25], where using a NMR quantum simulator, the geometric phase of an open system undergoing nonunitary evolution has been obtained. The GP was computed in a tomographic manner, measuring the off-diagonal elements of the reduced density matrix of the system. This study of the GP in the nonunitary regime is particularly important for the application of fault-tolerant quantum computation (see [34] as an example of measuring the Berry phase in a solid-state qubit where there is an important geometric contribution to dephasing that occurs when geometric operations are carried out in the presence of low-frequency noise).

In the present paper, we shall adopt a different model of decoherence than the one in [21]. We are concerned with non-equilibrium situations, in which the qubit (the main quantum system) is coupled to a non-equilibrium bath. The two-level quantum system presents an energy gap $E_2(t) - E_1(t) = \hbar \omega(t)$ which fluctuates due to the influence of the environment, where $E_j(t)$, with $j = 1, 2$ is the instantaneous energy of the state $j$ as perturbed by the surroundings. Following the idea proposed in [26], the bath is represented by a random function of time corresponding to the transition frequency of the two-state quantum system. In contrast to the usual treatment, the statistical properties of this random function are non-stationary, corresponding physically to, for example, impulsively excited phonons of the environment with initial phases that are not random, but which have defined values at $t = 0$. Due to this assumptions, this environment is not at thermal equilibrium. The time-dependent frequency is written in the form $\omega(t) = \Omega + \delta \omega(t)$, where $\delta \omega(t)$ is defined as

$$\delta \omega(t) = \sum_{k=1}^\infty c_k \cos(\omega_k t + \theta_k(t)).$$

(1)

The Fourier components $c_k$ are positive constants related to the spectral density of the environment and the coupling of the bath modes to the system. It is important to mention, that, in this model, the randomness enters through the non-stationary distribution of random phases $\theta_k(t)$, which are given by $\theta_k(t) = \theta_k(0) + x_k(t)$. The random function $x_k(t)$ satisfies a diffusion equation

$$\partial_t P_k(x, t) = D_k \partial_x^2 P_k(x, t)$$

(2)

where $P_k(x, t)$ is a time-dependent probability distribution and $D_k$ is the diffusion constant. The quantity $x_k$ is an angle, so $P(x, t)$ is a function with period $2\pi$. The time-dependent probability distribution for component
that solves Eq. (2) with an initial localized condition \( P(x, 0) = \delta(x) \) is

\[
P_k(x, t) = \frac{1}{2\pi} + \frac{1}{\pi} \sum_{n=1}^{\infty} e^{-n^2D_k t} \cos(nx). \tag{3}
\]

This means that, physically, the phase of each component of the random force is not random at \( t = 0 \), when an impulsive excitation creates a quantum coherence in the system, but decays to an uniform \( 1/2\pi \) distribution under diffusive evolution with diffusion constant \( D_k \). Following this approach, it is possible to evaluate

\[
\rho_{00}(t) = e^{-\alpha t} < \int_0^{\pi} \omega I(\omega) d\omega > \rho_{00}(0),
\]

the solution for the off-diagonal element of the density matrix (while the populations remain constant again).

By considering the typical factor \( f_k(t) = \exp(-i \int_0^t \omega k(s) ds) \), one has to do some algebra to obtain \( |F(t)| \). This mainly consists on performing the time integral and the averaging \( f_k(t) \) over the distribution probability \( P_k(x_k, t) \). After these computations, a simple but accurate approximation can be obtained, namely

\[
|F(t)| = |\prod_k f_k(t)| \approx e^{-\beta(t)}, \tag{5}
\]

with

\[
\beta(t) = \frac{1}{4} \int_0^\infty d\omega I(\omega) \times \left[ 1 - e^{-2\gamma t} + (e^{-\gamma t} - e^{-2\gamma t}) \cos(2\omega t + \theta(\omega)) \right]. \tag{6}
\]

It is important to note that in Eq. (5), the continuum limit has already been taken (in the number of bath modes) and the diffusion constant has been assumed \( D(\omega) = D \) for simplicity.

In order to study the decoherence process induced in the system by the presence of a non-equilibrium environment, we define a widely used physical spectral density \( I(\omega) = 4\gamma/\Lambda^2\omega^n/\Lambda^{n-1}e^{-\omega/\Lambda} \), where \( \gamma \) is the dimensionless dissipative constant and \( \Lambda \) is the cutoff frequency. On general grounds, \( \Lambda \) is the biggest frequency present in the environment, i.e. the frequency range of the environmental modes. In particular, the case with \( n = 1 \) is the “ohmic” case and the one with \( n > 1 \) is the “supraohmic” case. The ohmic environment is the most studied case in the literature, for example in the quantum Brownian motion paradigm, and produces a dissipative force that in the limit of the frequency cutoff \( \Lambda \rightarrow 0 \) is proportional to the velocity. The supraohmic case, on the other hand, is generally used to model the interaction between defects and phonons in metals and also to mimic the interaction between a charge and its own electromagnetic field (see for example \( \theta = \omega \)). In particular, the use of the supra-ohmic case can be used as a toy model to study decoherence process in quantum field theory.

This model of non-equilibrium is characterized by a key parameter which considers the effect of the initial phases of the bath modes in the function \( \theta(\omega) \). In this case, we consider a linear dependence such as \( \theta(\omega) = -\lambda\omega \). It is interesting to have the possibility to control dephasing by varying the single parameter \( \lambda \). Following Eq. (6), the decoherence factors can be exactly calculated and they are given by

\[
F_{\text{ohmic}} = e^{-\gamma e^{-\gamma t}(-1+e^{2\gamma t}) \left[ e^{2\gamma t} - 1 + 2\gamma e^{\gamma t} - \gamma^2 e^{2\gamma t} \right]}, \tag{7}
\]

for the ohmic case, and

\[
F_{\text{supra}} = e^{-\gamma e^{-\gamma t}(-1+e^{2\gamma t}) \left[ e^{2\gamma t} - 1 + 2\gamma e^{\gamma t} - \gamma^2 e^{2\gamma t} \right]}. \tag{8}
\]

It is interesting to analyse the asymptotic behaviour of the function \( \beta(t) \). Both types of non-equilibrium environments produce a linear time-dependence for the short time scale \( Dt \), \( \lambda t \ll 1 \), which induces a decoherence factor of the form \( F \sim \exp[-\gamma t] \) (where \( a \) is a constant with proper units). This is similar to the decoherence factor calculated in Ref. \( \theta = \lambda \) for the case of an ohmic finite temperature environment (just assuming that \( \gamma \sim \gamma_0 K_T^2 T \)). In this limit, decoherence is always an efficient process, unless the dissipative constant \( \gamma \) is very small. In the long time limit \( Dt \), \( \lambda t \gg 1 \), both \( \beta \) functions (the one for the ohmic, and the corresponding to the supraohmic cases) acquire a constant value (different for each type of environment). In this long time regime, decoherence factor in the ohmic case behaves as \( F \sim \exp[-\gamma] \), similar to the decoherence factor for the equilbium supraohmic environment at zero temperature. Meanwhile, in the supraohmic case, the decoherence factor approaches a long time value given by \( F \sim \exp[-6\gamma] \). Again, as we mentioned before, in the case of small \( \gamma \), decoherence never occurs, even at very long times. Intermediate times are ruled by the specific randomness introduced into the model. All in all, it is important to note the richness of the model which guarantees a known and unknown decoherence processes by the correct tuning of the parameters.

In Fig. (4) we present the behaviour of the decoherence factor for a strong dissipative case for both environments. As expected, the decoherence factor decays from unity to an asymptotic value. Then, we also present the behaviour of the decoherence factor found in \( \theta = \lambda \), where a different spectral density to describe the environment has been used. The parameters used in the Figure are similar to those used in \( \theta = \lambda \) in order to do a better comparison and analysis. Unlike typical studies using the master equation in the weak coupling limit (\( \gamma \sim e^2 t^2 \)), in
the present approach there is no constraint for the value of $\gamma$. Therefore we can use either a strong or weak coupling as a value for $\gamma$. In the Figure, we can note three different lines: the solid blue line for the results in [8], the red short-dashed line for our ohmic environment and the solid black long-dashed line for the supra-ohmic environment. Then, it is easy to see that the ohmic case is very similar to the one obtained in [8], where a Gaussian spectral density was considered. In both cases, decoherence is very efficient, as expected since we are considering the overdamped case ($\gamma \geq 1$). There is also an interesting fact: the supra-ohmic decoherence factor has a smaller decoherence time-scale than the other two decoherence factors herein considered. This is unlike the case for equilibrium supraohmic environment, where decoherence is effective only at high temperature. This modelling of the environment gives a decoherence factor which drops from its initial value toward an asymptotic value ($\mathcal{F}(t \to \infty)$) after the intermediate time $t = \lambda$. At this time the system re-phases back to the slowly decaying envelope without the non-monotonic dip (that occurs at $t = \lambda$). Non-exponential behaviour in the decay of quantum coherence has been observed in full many-particle simulations of quantum coherent dynamics under non-equilibrium conditions [29].

In order to have a better view of the dip where the system “recoheres” for a while, we present the behaviour of the decoherence factors for the weak coupling case in Fig. 3. Therein, $\gamma$ has a smaller value, comparable to those we used when dealing with environments in thermal equilibrium in the underdamped case [21, 30, 31].

The dip is obtained by introducing, as we mentioned before, the simple relation $\theta(\omega) = -\lambda \omega^2$ in an ohmic (blue solid line) and supraohmic (black solid line) environment. Parameters used: $\gamma = 3; \Lambda/\Omega = 1; \Omega \lambda = 1; D/\Omega = 0.1$.

FIG. 1. (Color online) Evolution in time of the decoherence factor $\mathcal{F}(t)$ for different models of the environment in the strong coupling limit. The red short-dashed line is for an ohmic non-equilibrium bath and the long-dashed black line is for the supraohmic. For $Dt, At \gg 1$, the decoherence factor behaves as $\mathcal{F}_{\text{ohmic}}(t) \sim \exp(-\gamma t)$ and $\mathcal{F}_{\text{supra}}(t) \sim \exp(-6\gamma t)$. We also present a solid blue line for the assumptions made in [8], a non-equilibrium bath with a Gaussian spectral density. Parameters used: $\gamma = 3; \Lambda/\Omega = 1; \Omega \lambda = 1; D/\Omega = 0.5$; and $n = 3$ for the supraohmic environment.

FIG. 2. (Color online) Evolution in time of the decoherence factor $\mathcal{F}(t)$ for different models of the environment in the weak coupling limit. The red short-dashed line is for an ohmic non-equilibrium bath and the black solid line is for the supraohmic case. We also present a solid blue line for the assumptions made in [8], a non-equilibrium bath with a Gaussian spectral density (different with respect to the normally used in the theory of quantum open systems theory). Parameters used: $\gamma = 0.5; \Lambda/\Omega = 1; \Omega \lambda = 1; D/\Omega = 0.1$.

FIG. 3. (Color online) A more complex modelling of the initial phases of the bath modes by considering $\theta(\omega) = -\lambda \omega^2$ in an ohmic (blue solid line) and supraohmic (black solid line) environment. Parameters used: $\gamma = 3; \Lambda/\Omega = 1; \Omega \lambda = 1; D/\Omega = 0.1$.
of the decoherence factor is somewhat more difficult and is not worth writing explicitly here. Anyway, the decoherence factor for a quadratic behaviour in $\omega$ is presented in Fig. 8 for an ohmic and supra-ohmic non-equilibrium environment. In such a case, it is important to note a more complicated structure of dips in the decoherence factor.

III. APPLICATION: GEOMETRIC PHASE FOR A QUBIT COUPLED TO A NON-EQUILIBRIUM ENVIRONMENT

In order to compute the GP and note how it is corrected by the environment, we shall briefly review the way the geometric phase can be computed for a system under the influence of external conditions such as an external bath. In Ref. 20, a quantum kinematic approach was proposed and the geometric phase (GP) for a mixed state under non-unitary evolution has been defined as

$$
\phi_G = \arg \left\{ \sum_k \sqrt{\varepsilon_k(0)\varepsilon_k(\tau)} \langle \Psi_k(0) | \Psi_k(\tau) \rangle \times e^{-\int_0^\tau dt \langle \Psi_k | \hat{H} | \Psi_k \rangle} \right\},
$$

(9)

where $\varepsilon_k(t)$ are the eigenvalues and $|\Psi_k\rangle$ are the eigenstates of the reduced density matrix $\rho_r$ (obtained after tracing over the reservoir degrees of freedom). In the last definition, $\tau$ denotes a time after the total system completes a cyclic evolution when it is isolated from the environment. Taking into account the effect of the environment, the system no longer undergoes a cyclic evolution. However, we shall consider a quasi cyclic path $P: t \in [0, \tau]$, with $\tau = 2\pi/\Omega$ ($\Omega$ is the system’s characteristic frequency).

\begin{figure}
\centering
\includegraphics[width=\textwidth]{fig4.png}
\caption{(Color online) Behaviour of the geometric phase as a function of the initial state of the quantum system $\theta_0$ (measured in radians) and the dissipation of the environment (dimensionless $\gamma$) induced by an ohmic non-equilibrium environment in a cycle. Parameters used: $\Lambda/\Omega = 1$; $\Omega \lambda = 1$; $D/\Omega = 0.1$.}
\end{figure}

Assuming an initial quantum state of the form

$$
|\psi(0)\rangle = \cos\left(\frac{\theta_0}{2}\right)|0\rangle + \sin\left(\frac{\theta_0}{2}\right)|1\rangle,
$$

(10)

its evolution at a later time $t$, is

$$
|\psi(t)\rangle = e^{-i\hat{H}t} |\psi(\theta_+)\rangle = \cos(\theta_+)|0\rangle + \sin(\theta_+)|1\rangle,
$$

(11)

where

$$
\cos(\theta_+) = \frac{\sin(\theta_0)|\mathcal{F}(t)|}{\sqrt{\sin^2(\theta_0)|\mathcal{F}(t)|^2 + 4(\varepsilon_+ - \cos^2(\theta_0/2))^2}},
$$

(12)

$$
\sin(\theta_+) = \frac{2(\varepsilon_+ - \cos^2(\theta_0/2))}{\sqrt{\sin^2(\theta_0)|\mathcal{F}(t)|^2 + 4(\varepsilon_+ - \cos^2(\theta_0/2))^2}},
$$

(13)

and $\varepsilon_+$ the eigenvalue of the reduced density matrix, namely

$$
\varepsilon_+ = \frac{1}{2}\left(1 + \sqrt{\cos^2(\theta_0) + \sin^2(\theta_0)|\mathcal{F}(t)|^2}\right),
$$

(14)

while $\varepsilon_-$ does not contribute to the geometric case since $\varepsilon_-(t = 0) = 0$ (see definition Eq.(9)).

As in our previous works 7, 21, 32, 33, the GP is obtained by computing eigenvectors and eigenvalues of the reduced density matrix and using Eq.(8),

$$
\phi_G = \Omega \int_0^\tau \cos^2(\theta_+) \, dt.
$$

(15)

In Figs. 4 and 5, we plot the environmentally induced correction to the unitary phase, $|\delta\phi_G|$ (normalized by the value of $\phi_U$) as a function of the system’s initial state $|\theta_0\rangle$ and the dissipation induced in the quantum subsystem due to the presence of the random environment ($\gamma$). In both Figures we have considered a wide range of values for $\gamma$, considering both weak and strong coupling between system and environment. For small values of $\gamma$, the GP behaves very similarly to the unitary GP which is $\phi_U = \pi(1 + \cos \theta_0)$. However, as we increase the value of $\gamma$, there is a notable change in the curvature as a function of $\theta_0$, leading to more values of $\theta_0$ with a null GP. As expected, the more decohering environment, the less survival of the GP. In agreement with Fig. 2, we can see that the geometric phase is less corrected (with respect to the isolated case) in the presence of an ohmic non-equilibrium environment rather than of a supraohmic one. This can be noted by the fact that

...
Fig. 4 remains a smooth function of $\theta_0$ for bigger values of $\gamma$ than Fig. 5, in which case the phase rapidly behaves different as a function of the dissipation constant. The GP cannot be fully computed analytically but we can perform an expansion in powers of the coupling constant, to obtain an accurate approximation of it [21–23].

Hence, we expand in powers of $\gamma$ the $\cos^2 \theta$ in Eq. (15), using the definition of the decoherence factors for each environment, namely Eqs. (7) and (8). As mentioned before, the correction to the GP is defined as $\delta \phi_G$, while $\phi_U$ is the unitary GP. In the case of the ohmic nonequilibrium environment, the correction to the unitary GP is given by,

$$
\delta \phi_{G,\text{ohm}} \approx \pi \gamma \sin^2(\theta_0) \cos(\theta_0) + \gamma \frac{\Omega D}{\Lambda^3} e^{-2\Lambda \gamma} \sin^2(\theta_0) \cos(\theta_0).
$$

(16)

Proceeding the same way for the supraohmic environment, the correction to the unitary GP is

$$
\delta \phi_{G,\text{supra}} \approx 6 \pi \gamma \sin^2(\theta_0) \cos(\theta_0) + \gamma \frac{\Omega D^3}{4\Lambda^4} e^{-2\Lambda \gamma} \sin^2(\theta_0) \cos(\theta_0).
$$

(17)

The corrections of the GP for both environments agree for small values of $\gamma$ in Figs. 4 and 5. In both cases, the dependence with the parameter $\lambda$ is exponentially negligible. Another interesting feature of the corrections of the GP is that they depend on the initial angle of the quantum state, and this dependence is in agreement with the ones obtained for a two-level system in interaction with environments at equilibrium [7, 21–23, 32, 33].
IV. FINAL REMARKS

The geometric phase of quantum states is an issue worth of attention. It could be a potential application in holonomic quantum computation since the study of spin systems effectively allows us to contemplate the design of a solid state quantum computer. However, decoherence is the main obstacle to overcome. All realistic quantum systems are coupled to their surroundings to a greater or lesser extent. Furthermore, in most cases of practical interest, quantum systems are subjected to many noise sources with different amplitudes and correlation times, corresponding de facto to a non-equilibrium environment.

Herein, we have presented a simple case to illustrate the general phenomenon of dephasing in a non-equilibrium bath. We have studied the decoherence process of a quantum system in interaction with an initially non-equilibrium bath that can be controlled by manipulating the nature of the relative initial phases of the bath modes. The decoherence factors computed here suggest that by engineering these initial phases, the dephasing of the subsequent quantum evolution can potentially be controlled. We have found similarities and differences of the decoherence process between the environment presented here and thermal environments studied in previous works. The model presented here is another proposal for engineering reservoirs in a manner reminiscent of a coherent control experiment using shaped pulses. In this model, the control parameter $\lambda$ is derived not from a laser pulse, but rather from well-defined phase relations between the modes of the bath. Another possible candidate for realizing this decoherence environment, is to use the artificially generated fluctuating environments with NMR. It could be possible, in principle, to use the quantum simulator of Ref. to generate the fluctuating phase $\theta(\omega)$ of the present proposal.

The analysis of the effect produced by decoherence on the GP is crucial at the time to design an experimental setup to measure the GP using, for example, interferometry. We found that the convenient non-equilibrium environment to observe GPs is the weak coupled ohmic case. It is important that there is no restriction about zero temperature environments in this case, as it was found in [21], as the most convenient scenario. In this framework, these kind of environments could become a proper experimental setup for the observation of the geometric phase. Therefore, we have computed the geometric phase for an ohmic and supra-ohmic non-equilibrium environment and seen how they deviate from the unitary geometric phase. So far, we have seen that the characteristic dip of the decoherence factor does not affect much the geometric phase and that ohmic non-equilibrium environment are not as destructive as the supraohmic non-equilibrium ones or the thermal environments we are so used to see in the literature. The effect done on the geometric phase by the ohmic (or/supraohmic) non-equilibrium environment can be seen as similar to the one done by a single reservoir with an effective temperature, as the non-equilibrium environment model proposed in [3]. In the very weak coupling limit, we have evaluated the corrections induced by the non-equilibrium environment on the unitary GP, showing that there is a small (exponentially suppressed) correction due to the random parameter $\lambda$. More general models should be analysed in a future work.
