Three body photodissociation of the water molecule and its implications for prebiotic oxygen production

Yao Chang, Yong Yu, Feng An, Zijie Luo, Donghui Quan, Xia Zhang, Xixi Hu, Qinming Li, Jiayue Yang, Zhichao Chen, Li Che, Weiqing Zhang, Guorong Wu, Daiqian Xie, Michael N. R. Ashfold, Kaijun Yuan & Xueming Yang

The provenance of oxygen on the Earth and other planets in the Solar System is a fundamental issue. It has been widely accepted that the only prebiotic pathway to produce oxygen in the Earth’s primitive atmosphere was via vacuum ultraviolet (VUV) photodissociation of CO₂ and subsequent two O atom recombination. Here, we provide experimental evidence of three-body dissociation (TBD) of H₂O to produce O atoms in both 1D and 3P states upon VUV excitation using a tunable VUV free electron laser. Experimental results show that the TBD is the dominant pathway in the VUV H₂O photochemistry at wavelengths between 90 and 107.4 nm. The relative abundance of water in the interstellar space with its exposure to the intense VUV radiation suggests that the TBD of H₂O and subsequent O atom recombination should be an important prebiotic O₂-production, which may need to be incorporated into interstellar photochemical models.
Oxygen is the third most abundant element in the Universe, but its molecular form (O2) is very rare. Besides on the Earth, molecular oxygen has only been detected in two interstellar clouds1,2, in the moons of Jupiter3 and Saturn4, and on Mars5. Geologically based arguments suggested that Earth’s original atmosphere had no oxygen and was composed mostly of H2O, CO2, and N2, with only small amounts of CO and H2. Therefore, how oxygen is produced in the primitive atmosphere is a fundamentally important issue in the evolution of the early primitive atmosphere. Before the emergence of the oxygen-rich atmosphere due to the “great oxidation event”6,7,8, about 2.33 billion years ago, which allowed the Earth to evolve into a living planet, a small amount of oxygen was already present, and this was previously attributed to an abiotic formation mechanism involving photodissociation of CO2 by vacuum ultraviolet (VUV) light, followed by three-body recombination processes9:

\[
\text{CO}_2 + h\nu \rightarrow \text{CO} + \text{O} \quad (1)
\]

\[
\text{O} + \text{O} + \text{M} \rightarrow \text{O}_2 + \text{M} \quad (2)
\]

where M is a third body to carry off the excess energy in the reaction process. Direct O2 production pathways via VUV photodissociation of CO210 and dissociative electron attachment to CO211 have recently been identified. These findings provide new insights into the sources of O2 in Earth’s early atmosphere.

In contrast, photodissociation of H2O, one of the dominant oxygen carriers12, has long been assumed to proceed mainly to produce hydroxyl (OH) and hydrogen (H) atom primary products, and contribute limitedly to the O2 production9. Recently, abundant molecular O2 in the coma of comet 67P/Churyumov–Gerasimenko, which is dominated by H2O, CO, and CO2, has been detected13. Interestingly, a strong correlation between O2 and H2O has been identified, indicating the O2 formation is linked to H2O in the comet. One plausible explanation for the strong O2–H2O correlation would be that the O2 is produced by radiolysis or photoysis of water, or single collisions of energetic H2O+ with surfaces14. However, the existing photochemical reaction mechanisms underestimate the O2 abundance13. Thus, the detailed O2 production mechanism in the coma of comets is still unclear.

The photodissociation of water has been the subject of many experimental studies, which have revealed fascinating dynamics arising from strongly coupled electronic states with strikingly different potential energy surfaces (PESs)15,16. Excitation to the first excited singlet (A1B1) state of H2O at wavelengths ~160 nm results in direct O–H bond fission yielding an H atom plus a ground state hydroxyl radical, OH(X2Π), with little internal excitation17–19. The absorption cross-section to the second excited singlet (B1A1) state is maximal at λ ~128 nm. Excitation at these wavelengths results in a (minor) direct dissociation channel to electronically excited OH(A2Σ+)+H products. The major dissociation process yields ground state OH(X)+H products following non-adiabatic transitions at conical intersections between the B and X state PESs at linear H–O–H and H–H–O geometries20–23.

Additional fragmentation pathways, named three-body dissociation (TBD), become accessible energetically at shorter photolysis wavelengths, e.g.:

\[
\text{H}_2\text{O} + h\nu \rightarrow \text{O}(^3\Pi) + \text{H} + \text{H} \rightarrow (9.513 \text{ eV}) \quad (3)
\]

\[
\rightarrow \text{O}(^1\Delta) + \text{H} + \text{H} \rightarrow (11.480 \text{ eV}) \quad (4)
\]

where the threshold energies (Eth) for these fragmentation channels are given in parentheses (on the basis of thermodynamic calculations with the data available from the thermochemical network) (https://atct.anl.gov). Fragmentation channel (3) has been previously detected with small quantum yields24,25 following photoexcitation of H2O at the Lyman-a wavelength (λ = 121.57 nm). Because of the lack of intense tunable VUV laser sources, the quantitative assessment of the importance of the H2O TBD processes in the VUV region and its role in the O2 formation in the interstellar space has not been possible. Recent development of the intense VUV free electron laser, at the Dalian Coherent Light Source (DCLS), has provided an exciting tool for experimental studies of molecular photochemistry throughout the entire VUV region26.

Herein we report the studies of the H2O photochemistry in the VUV region using the DCLS and the H-atom Rydberg tagging time-of-flight (HRTOF) technique. These experiments allow quantitative determination of the relative importance of the binary dissociation and the TBD processes following photoexcitation of H2O in the 90–110 nm region. The present results show conclusively that the H2O TBD process is an important pathway to form oxygen in the interstellar space.

Results and discussion

The H2O sample was generated in a supersonic beam, with a rotational temperature estimated to be about 10 K. The H2O molecules were photoexcited to different Rydberg states27 (see Supplementary Fig. 2 and Supplementary Note 2). The dissociated H atom fragments were then detected using the HRTOF technique (see Supplementary Fig. 1 and Supplementary Note 1). TOF spectra of the H atoms resulting from H2O photodissociation at λ = 107.4 nm have been recorded, with the detection axis aligned parallel and perpendicular to the polarization vector of the VUV-FEL radiation. Knowing both the distance traveled by the H atom from the photodissociation area to the detector and its mass, the TOF spectra can be converted into the distributions of total kinetic energy release (TKER), which is derived using the following equation, \( E_{\text{KE}} = \frac{1}{2} m_H t^2 + \frac{m_H}{m_O} \frac{d^2}{2} \), where \( d \) is the flying path length of H atom (d = 28 cm) from the photodissociation region to the detector, t is the measured time of flight28. Using the TKER distributions obtained in the parallel and perpendicular directions, we can construct a 3-dimensional (3D) flux diagram of the H atom fragments. Figure 1 shows the 3D product flux diagrams in two regions of the kinetic energy with rich structures. The tall feature at low kinetic energy (Fig. 1A) shows a large product angular anisotropy, whereas the product anisotropy in the higher kinetic energy region (Fig. 1B) is rather small.

For detailed analysis and feature assignment, the TKER distributions in parallel and perpendicular directions at λ = 107.4 nm are plotted in Fig. 1C, while the product TKER distribution from photodissociation of H2O at the magic angle (with detection angle of 54.7° relative to the polarization direction) is shown in Fig. 1D. These distributions show both sharp and broad features. Using the energy conservation relationship appropriate for a binary photodissociation process:

\[
E_{\text{th}} + E_{\text{int}}(\text{H}_2\text{O}) = D_0(\text{H} – \text{OH}) + E_{\text{KE}}(\text{H} + \text{OH}) + E_{\text{int}}(\text{OH})
\]

(5)

where \( E_{\text{int}}(\text{H}_2\text{O}) \) and \( E_{\text{int}}(\text{OH}) \) are the internal energies of H2O and OH, respectively, \( E_{\text{KE}} \) is the product total kinetic energy and \( D_0(\text{H} – \text{OH}) \) is the dissociation energy of H2O29. We can assign all of the sharp structures to specific ro-vibrational levels of the OH product in the X and A states formed via the binary dissociation channel, \( \text{H} + \text{OH} \) (or A, v, N). In addition to these sharp structures, the TKER spectra show two broad features: one with \( E_{\text{KE}} \leq 600 \text{ cm}^{-1} \) that has a large angular anisotropy, and an underlying feature that spans the range of \( 600 \leq E_{\text{KE}} \leq 16,000 \text{ cm}^{-1} \) which displays a much smaller angular anisotropy. These broad features are obviously not from the binary dissociation channel, \( \text{H} + \text{OH} \). Based on energy conservation, the maximum kinetic energy for the H atom product...
from the TBD channels (3) and (4) at 107.4 nm are 16,448 and 580 cm$^{-1}$, respectively. These limits of the two TBD channels match well with the upper limits of the two broad features in the distributions (Fig. 1). Thus, the intense broad feature at $E_{KE} < 600$ cm$^{-1}$ is assigned to the O(1D) + 2H channel, while the broad underlying signal extending to $E_{KE} \sim 16,000$ cm$^{-1}$ is attributed to the O(3P) + 2H products.

Given the above analysis, the product TKER distribution in Fig. 1D can be divided into three components: O(1D) + 2H, O(3P) + 2H, and OH + H. The first two components are broad features, while the third comprises sharp structures attributable to ro-vibrational levels of the OH(A) and OH(X) products. From Fig. 1D, the O(1D) + 2H channel obviously has the highest intensity in the kinetic energy <600 cm$^{-1}$, yet it has never been reported previously in H$_2$O photodissociation. The O(3P) + 2H channel clearly makes the major contribution in the higher kinetic energy region. This indicates that the TBD is likely the dominant process following VUV photoexcitation of H$_2$O at 107.4 nm.

Branching ratios for the O(1D) + 2H, O(3P) + 2H, and OH + H fragmentation channels have been estimated by simulating the TKER distribution (Fig. 1D) using the three components shown in Fig. 2. Integrating the areas under the respective distributions returns relative H atom yields for the three channels. Recognizing that two H atoms are formed in each TBD process, the relative H atom yields are used to determine the branching ratio, e.g. 67% at 107.4 nm for the TBD channels (Table 1).

Photodissociation of H$_2$O has also been investigated at eight more VUV wavelengths between 92 and 109 nm, and a similar data analysis procedure is applied at these photolysis wavelengths (Supplementary Fig. 3 and Supplementary Note 3). The branching ratios determined for the binary and TBD channels at each wavelength are listed in Table 1. At 109.0 nm, only one TBD channel (O(3P) + 2H) exists because the O(1D) + 2H channel is energetically not accessible. The results mean that oxygen atoms (1D and 3P), not OH radicals, are the major oxygen-containing products from H$_2$O photolysis at $\lambda < 107.4$ nm, in striking contrast to the dominant binary photofragmentation (i.e. H + OH) behavior displayed by H$_2$O photochemistry at longer VUV wavelengths.

The dissociation dynamics of the two TBD channels are also quite interesting. Since the two H atoms in the water molecule are equivalent, if they dissociate simultaneously it should yield a narrow H atom kinetic energy distribution, peaking at an $E_{KE}$ value close to half of the available energy (Supplementary Figs. 5 and 6 and Supplementary Note 5). However, the observed distributions are much broader than the narrow distributions for a simultaneous concerted process, implying that both TBD processes are due to mostly a sequential dissociation mechanism. Possible dissociation routes for the two channels are illustrated in Fig. 3 (and more details in Supplementary Fig. 7 and Supplementary Note 6). The water molecule undergoes efficient non-adiabatic coupling from the initial excited $nd$ Rydberg states to the D state. Path 1 illustrates the possible direct dissociation route from the D state to form O(1D) + 2H products. The overall anisotropy parameter of this channel is about 0.8, according with a fast and direct dissociation process. Paths 2 and 3 illustrate plausible routes for the more complicated O(3P) + 2H dissociation paths: from the D state to the B state and then to the ground state via the two CIs between the $B$ and $X$ state PESs, following the initial internal conversion from the excited $nd$ Rydberg states to the D state. The averaged anisotropy parameter of this channel...
is considerably smaller (~0.2). This also accords with the dissociation undergoing several internal conversions, and with the more scrambling that leads to small product anisotropy.

The conclusion that the TBD is the dominant decay process following excitation of H$_2$O at these VUV wavelengths could have profound implications for our understanding of the source of oxygen production. For quantitative assessment, we have calculated the fragment-dependent photodissociation rate of H$_2$O by using: $J_{H2O} = f \Phi_n \Gamma \Phi_{\lambda} d\lambda$, where $\Phi_n$ is the solar photon flux, $\Gamma$ is the fragment quantum yield, and $\Phi_{\lambda}$ is the photodissociation cross-section\textsuperscript{30}. Figure 4 collects together the wavelength dependences of the solar photon flux and the total photodissociation cross-sections of the parent H$_2$O molecule in the VUV region (90–200 nm)\textsuperscript{33} and the production yields of O atoms at studied photolysis wavelengths. Convoluting the solar photon flux, the photodissociation cross-sections, and the production yields implies that ~21% of the photoexcitation events of H$_2$O will result in O atoms. Considering the water abundance in widely interstellar circumstances, like in interstellar clouds\textsuperscript{33} and in the moons of planets in the Solar System (e.g., the comets 67P\textsuperscript{1,33}), oxygen production from the water photolysis should be an important process. The following recombination of oxygen atoms will produce molecular oxygen.

In addition, it is well known that the water photolysis has nothing to do with oxygen production in the Earth’s atmosphere under equilibrium conditions due to VUV photon screening by the thick atmosphere\textsuperscript{30,34}. However, in the earliest period of Earth, i.e., the period approaching to element conditions on the earliest Earth followed by the current Earth–Moon system formed, the surface of Earth remained quite hot (>1000 K)\textsuperscript{34}, all of the water on the Earth was vaporized to the atmosphere and part of water clouds (emitted from volcanos or delivered by carbonaceous chondrite meteorites\textsuperscript{6}) populated at the top of the atmosphere could absorb the VUV photons and dissociate. Given [H$_2$O]$^+$ is ten times abundant than [CO$_2$] in the atmosphere during this early, chaotic period of Earth\textsuperscript{6} (see Supplementary Fig. 4 and Supplementary Note 4), the O production rate from H$_2$O VUV photochemistry could be three times larger than that of CO$_2$ in the same VUV wavelength region, via TBD processes: $N_{H_2O}(O)/N_{CO_2}(O) = (I_{H_2O}(O) \times [H_2O])/ (I_{CO_2}(O) \times [CO_2]) \approx 3$, where $I_{H_2O}(O) = 5.2 \times 10^{-5}$ s$^{-1}$ (Fig. 4), $I_{CO_2}(O) = 1.8 \times 10^{-4}$ s$^{-1}$ (Supplementary Fig. 8 and Supplementary Note 7). [H$_2$O] and [CO$_2$] are the densities of H$_2$O and CO$_2$ respectively. Since the molecular oxygen generation process should be the same in the three-body recombination process (Eq. (2)), this analysis implies that the H$_2$O photochemistry might be an important prebiotic source of O$_2$ in Earth’s early atmosphere.

From the experimental results, it seems that more than one-third of O atoms produced from H$_2$O TBD process populate in the metastable 1D state. The generation of O(1D) atoms from photodissociation of H$_2$O in a significant amount is also very interesting because the metastable 1D atom is highly reactive\textsuperscript{35}. It can react with almost all the gases emitted into the atmosphere. For instance, the reaction of O(1D) with methane could be a significant source of formaldehyde in the earth’s primitive atmosphere\textsuperscript{36,37}. Thus, the production of O(1D) atoms from the exposure of water to VUV radiation, and the subsequent reactions of these atoms, could have been important drivers in the evolution of the earliest atmosphere.

In the existing interstellar photochemical model, reactions (1) and (2) are the major pathways to produce prebiotic O$_2$. In this work, we propose an alternative prebiotic O$_2$ pathway: atomic oxygen production from the TBD of water, followed by oxygen recombination reactions. Recent International Ultraviolet Explorer satellite observation of pre-main-sequence stars suggested that the nascent Sun has emitted more than ten times VUV radiation than it does today\textsuperscript{38}. This implies that oxygen formation by VUV photoinduced TBD of H$_2$O is likely an

**Table 1** The branching ratios for the binary and TBD channels following the H$_2$O photodissociation at different VUV wavelengths (nm).

| Dissociation channel | Photolysis wavelength (nm) | 109.0 | 107.4 | 106.7 | 105.7 | 101.3 | 98.1 | 96.2 | 94.5 | 92.0 |
|----------------------|-----------------------------|-------|-------|-------|-------|-------|------|------|------|------|
| TBD (O($^3$D)/$^3$P + 2H) | 0.35 | 0.67 | 0.76 | 0.62 | 0.77 | 0.72 | 0.79 | 0.86 | 0.86 |
| Binary dissociation: (H + OH) | 0.65 | 0.33 | 0.24 | 0.38 | 0.23 | 0.28 | 0.21 | 0.14 | 0.14 |

The maximum uncertainty on the branching ratios is ±10%.
important process in the coma of comets, in the interstellar clouds and even in Earth’s primitive atmosphere, and thus needs to be incorporated into interstellar photochemical models. Furthermore, the TBD of H₂O may well be important for the oxygen evolution in the atmospheres of all water-rich terrestrial planets.³⁹

Methods

Vacuum ultraviolet free electron laser (VUV-FEL) radiation. The experiments employ a recently constructed apparatus for molecular photochemistry, which is centered on the VUV-FEL beam line at the DCLS²⁶. The VUV-FEL facility runs in a multichannel scaler. The signal detected by the MCP is amplified by a fast preamplifier, fed by a known distance (d ≈ 280 mm) from the interaction region to a rotatable microchannel plate (MCP) Z-stack detector located close behind a grounded fine metal grid. After passing through the grid, the Rydberg atoms are immediately field-ionized by the electric field (~2000 V/cm) applied between the grid and the front plate of the Z-stack MCP detector. The signal detected by the MCP is amplified by a fast preamplifier and counted by a multichannel scaler.
