The primary site of mercury-induced injury is the kidney due to uptake of the reactive Hg\(^{2+}\)-conjugated organic anions in the proximal tubule. Here, we investigated the in vivo role of Oat1 (organic anion transporter 1; originally NKT (Lopez-Nieto, C. E., You, G., Bush, K. T., Barros, E. J., Beier, D. R., and Nigam, S. K. (1997) J. Biol. Chem. 272, 6471–6478)) in handling of known nephrotoxic doses of HgCl\(_2\). Oat1 (Slc22a6) is a multispecific organic anion drug transporter that is expressed on the basolateral aspects of renal proximal tubule cells and that mediates the initial steps of elimination of a broad range of endogenous metabolites and commonly prescribed pharmaceuticals. Mercury-induced nephrotoxicity was observed in a wild-type model. We then used the Oat1 knock-out to determine in vivo whether the renal injury effects of mercury are mediated by Oat1. Most of the renal injury (both histologically and biochemically as measured by blood urea nitrogen and creatinine) was abolished following HgCl\(_2\) treatment of Oat1 knock-outs. Thus, acute kidney injury by HgCl\(_2\) was found to be mediated mainly by Oat1. Our findings raise the possibility that pharmacological modulation of the expression and/or function of Oat1 might be an effective therapeutic strategy for reducing renal injury by mercury. This is one of the most striking phenotypes so far identified in the Oat1 knock-out. (Eraly, S. A., Vallon, V., Vaughn, D. A., Gangoiti, J. A., Richter, K., Nagle, M., Monte, J. C., Rieg, T., Truong, D. M., Long, J. M., Barshop, B. A., Kaler, G., and Nigam, S. K. (2006) J. Biol. Chem. 281, 5072–5083).

Environmental exposure to mercury represents a major threat in an increasingly industrialized world. Children exposed to high levels of the metal before and after birth suffer from choorea, ataxia, seizures, tremors, and mental retardation (2, 3). The ingestion of mercury-contaminated seafood represents the major source of exposure, although other sources such as many manufacturing processes, salvaging of electronics, and mining practices (particularly in the developing world) contribute to the accumulation of heavy metals in the environment. Metallic mercury, methyl mercury, and ethyl mercury are neurotoxic compounds that can be converted in the body to inorganic mercury, which is highly nephrotoxic. Mercuric (Hg\(^{2+}\)) ions are found in the plasma primarily as conjugates of thiol-containing biomolecules such as glutathione, cysteine, homocysteine, N-acetylcysteine, and albumin. Mercuric S-conjugates of these thiols are considered primary substrates for transport by the proximal tubule cells of the kidney (4, 5).

Although the renal transport of mercury and the mechanism of renal toxicity are not well characterized, accumulating evidence suggests that the uptake is mediated, at least in part, via the organic anion transporter system (6). Oat1, which was originally identified as NKT by us (1), is expressed on the basolateral membrane of proximal tubular cells and is a multispecific organic solute transporter mediating the initial steps of elimination of various substrates, including nutrients, drugs, toxins and metabolites, from the circulation (7–9). In vitro assays demonstrated that Oat1 is able to mediate the uptake of mercuric compounds such as conjugates of homocysteine, cysteine, N-acetylcysteine, and glutathione (10–12). Moreover, p-aminohippurate (a high affinity competitive substrate transported by this organic anion/dicarboxylate exchanger) and probenecid (an Oat1 inhibitor) can block the uptake of mercuric conjugates (13, 14). Nevertheless, in vivo evidence directly linking mercury toxicity and an individual Oat transporter is lacking. In this study, we investigated the mercury-induced renal injury in both rats and Oat1\(^{-/-}\) mice by intraperitoneal administration of 4 mg/kg of body weight of HgCl\(_2\). Our results indicate that, although the rodents are susceptible to mercury, mice deficient in Oat1 due to genetic deletion are largely protected from the mercury-induced kidney injury. This is consistent with the notion that Oat1 is the major transporter mediating cellular uptake of mercuric conjugates and provides direct genetic evidence implicating Oat1 in the renal injury from HgCl\(_2\) by mediating its transport into the proximal tubular cells.

**EXPERIMENTAL PROCEDURES**

In Vivo Studies (16)—Wistar Rats (110–150 days of age) were treated with a single injection (intraperitoneal) of HgCl\(_2\) at a nephrotoxic dose of 4 mg/kg of body weight (w/v in 1 ml of saline/kg; HgCl\(_2\) group, n = 4) (4). All experiments were performed in accordance with the Guide for the Care and Use of Laboratory Animals of the National Institutes of Health (Bethesda, MD) and were approved by the local animal ethics committee. Controls (control group, n = 4) received the vehicle...
After 18 h of HgCl₂ treatment as described above, urine, C57BL/6J controls were used in the experiments described. A total of 10 generations. Nevertheless, a major environmental source is inorganic mercury, in which mercury is transported by the kidney (Table 1). Nevertheless, a major environmental source is inorganic mercury, in which mercury is transported by the kidney (Table 1). Evidence indicates that mercuric conjugates are the major form of mercury excreted in urine and plasma samples. Blood urea nitrogen (BUN)² levels were evaluated in plasma samples. Creatinine and BUN concentrations were assayed employing commercial kits (QuantiChrom™, BioAssay Systems, Hayward, CA). Creatinine clearance was calculated by conventional formulas for each animal.

Mice between 12 and 20 weeks of age (matched within 2 weeks) with the Oat1 null allele were backcrossed with C57BL/6J mice for a total of 10 generations. Oat1-knockout mice and wild-type C57BL/6J controls were used in the experiments described. After 18 h of HgCl₂ treatment as described above, urine, blood, and tissues were collected. The plasma was separated by centrifugation (3000 rpm, 3 min). BUN concentrations were evaluated in plasma samples. Creatinine and BUN concentrations were assayed employing commercial kits (QuantiChrom™, BioAssay Systems, Hayward, CA).

Histological Studies—Kidneys were rinsed with 0.9% saline, fixed in 4% paraformaldehyde for 24 h, transferred to 70% ethanol, processed, and finally embedded in paraffin. 5-μm sections were cut and stained with hematoxylin and eosin for histological examination using a light microscope.

Materials—Chemicals were purchased from Sigma and were analytical grade.

Statistical Analysis—Statistical analysis was performed using an unpaired t test. When variances were not homogeneous, Welch’s correction was employed. p values <0.05 were considered significant. Values are expressed as means ± S.E.

RESULTS

HgCl₂-induced Renal Insufficiency—A substantial body of evidence indicates that mercuric conjugates are the major form in which mercury is transported by the kidney (Table 1). Nevertheless, a major environmental source is inorganic mercury, even though it is believed to be eliminated as mercury organic conjugates transported predominantly by Oat1 (see “Discussion”). HgCl₂ treatment is a well-established model for studying this process in vivo (11, 16). Thus, treatment of rats with HgCl₂ significantly increased plasma BUN levels (Table 2), suggesting impairment of renal function. In addition, blood and urine chemistry analyses revealed significant renal disturbance under the HgCl₂-treated conditions. When both HgCl₂-treated and vehicle-treated rats were placed in metabolic cages for 18 h immediately following the injection, significantly reduced amounts of urine were excreted by the HgCl₂-treated rats versus the controls treated with vehicle alone. This was accompanied by a reduction in the clearance of creatinine, further supporting the notion that HgCl₂ treatment results in renal impairment. Fig. 1 shows that the ratio of kidney weight to body weight was increased (Fig. 1A) and that the urine volume (Fig. 1B) and clearance of creatinine (Fig. 1C) were decreased in the HgCl₂-treated rats.

 Tubular Damage following HgCl₂ Exposure—To confirm that the physiological disturbance observed was of renal tubular origin, kidneys from both the HgCl₂-treated and control rats were examined histologically. Examination of hematoxylin/eosin-stained rat kidney slices 18 h after HgCl₂ treatment revealed dilated tubular lumina, disrupted tubular basement membranes, sloughing of cells, and intratubular cast formation (Fig. 2), suggesting early stages of tubular necrosis that are consistent with acute kidney injury. When the relative diameter of the lumen was measured, significant increases in the width of the lumen in tubules was found in HgCl₂-treated rats compared with vehicle-treated controls. Thus, histopathological data are consistent with pathophysiological analyses showing that a single dose of 4 mg of HgCl₂/kg of body weight is sufficient to cause proximal tubular injury within 18 h.

Significantly Reduced Renal Injury and Insufficiency in Oat1 Knock-outs after HgCl₂ Exposure—The kidney is a primary target organ of mercury injury. Studies in vitro have suggested that mercury-induced renal injury could be mediated by organic anion transporters (10–12). We thus sought to confirm this in vivo by treating mice deficient in Oat1 with HgCl₂ in a manner similar to that described above for rats. The Oat1 coding sequences in mice and rats are extremely similar (17), and it is known that similar substrates are transported (18). As in the case of the rat, treatment of wild-type mice with 4 mg of HgCl₂/kg of body weight (intraperitoneal) led to a significant increase in the ratio of kidney weight to body weight (Fig. 3A). In addition, significant increases in plasma BUN levels were also observed in wild-type (C57/BL6) mice following HgCl₂ treatment (Fig. 3B). These data are consistent with the phenotypes observed in rats upon similar treatment.

To obtain direct evidence regarding the role of Oat1 in the renal injury induced by mercury, Oat1/Slc22a6 knock-outs (backcrossed to C57/BL6) were subjected to treatment with 4 mg of HgCl₂/kg of body weight (intraperitoneal; same conditions as for the wild-type mice; see above). Following treatment with HgCl₂, there was a slight increase in the ratio of kidney weight to body weight in Oat1-deficient mice compared with

vehicle-treated wild-type mice. However, this increase was much smaller than that observed in HgCl₂-treated wild-type mice (Fig. 3A).

In contrast to wild-type mice treated with HgCl₂, no significant increase in the plasma BUN level was observed in Oat1⁻/⁻ mice treated with HgCl₂ (Fig. 3B). These data suggest that mercury-induced renal insufficiency is markedly reduced in mice deficient in Oat1/Slc22a6.

Reduced Tubular Histopathological Damage in Oat1⁻/⁻ Kidneys after HgCl₂ Exposure—Histopathological damage as assessed by hematoxylin and eosin staining of kidney sections revealed a marked difference in the pattern of renal injury between wild-type and Oat1 knockout mice (Fig. 4). The wild-type kidneys showed proximal tubular necrosis characterized by dilated tubular lumina with retention of urine and loss of the epithelial brush border with pyknotic nuclei. These signs of renal injury were virtually undetectable in the Oat1 knockout kidneys (Figs. 4 and 5). Our functional and histopathological data indicate that Oat1/Slc22a6 is a direct mediator of mercury renal injury and that its deletion in Oat1⁻/⁻ mice is responsible for the remarkable reduction in HgCl₂-induced proximal tubular necrosis (Fig. 6).

DISCUSSION

Mercury accumulates preferentially in kidneys and can cause kidney injury (19). In this study, a single injury dose of HgCl₂ induced significant renal impairment in rodents. This HgCl₂-induced renal insufficiency is caused by proximal tubular injury mediated mainly by the renal organic anion transporter Oat1/Slc22a6.

Inorganic mercury has been recognized as a hazardous environmental pollutant; nevertheless, it is still used in some batteries and continues to be an essential component of fluorescent light bulbs (20). People can be exposed to mercury through contaminated water and food (21). Moreover, different mercury species (vapor, inorganic mercury, and methyl mercury) have been associated with human contamination in gold-mining areas (22, 23).

Renal proximal tubular cells represent the primary target site where highly reactive mercuric ions rapidly accumulate and induce cell injury by binding to and inhibiting various sulfhydryl-containing enzymes (4). Complex factors may account for this susceptibility, including the selective presence of specific transport systems involved in the uptake of mercuric ions by particular cell populations (6). The extraction of mercury from renal tubular cells does not appear to involve glomerular filtration but rather a direct secretory process whereby mercury moves from peritubular blood into the tubular lumen (24). Mercury is believed to access proximal tubular cells primarily via the organic anion transporters found on the basolateral
plasma membrane (12, 13, 16); however, direct in vivo evidence for this has not been available so far.

Oat1 is expressed in the proximal tubules of the kidneys, where it plays an important role in the elimination of numerous organic anions of physiological (25), pharmacological, and toxicological (9, 17, 26–30) relevance. Although we have detected inhibition by HgCl₂ of the transport of 6-carboxyfluorescein (an Oat1 substrate), the in vivo physiological relevance of this finding and whether inorganic mercury is a true Oat1 substrate are not clear (data not shown). The bulk of published evidence supports the view that inorganic mercury is converted to an organic form before being transported by Oat1. In vitro assays indicate that Oat1 mediates the uptake of a number of mercuric conjugates, including homocysteine, cysteine, N-acetylcysteine, and glutathione (Table 1) (10–12, 31).

In this study, we have provided direct evidence that Oat1 is a mediator of HgCl₂ renal injury in vivo. For example, the observed increase in kidney weight (presumably due to edema) (27, 32–34) and BUN levels seen in rats and wild-type mice following HgCl₂ treatment was lessened dramatically in the Oat1−/− mice, suggesting a role for Oat1 in the uptake of mercuric conjugates from the blood and into the renal epithelial cells. In addition, other parameters of renal function perturbed by HgCl₂ treatment were also less affected in the Oat1 knock-out mice. For example, BUN levels were largely similar to control levels, whereas histological parameters (35–37) were largely unchanged in the Oat1−/− kidney following HgCl₂ treatment. These differences in renal injury are striking and indicate that Oat1 is the main transporter responsible for HgCl₂-induced renal injury. This is also one of the most impressive phenotypes reported in the Oat1 knock-out.

It is worth noting that the expression of Oat3 is somewhat reduced in the Oat1 knock-out kidney, but this appears to be physiologically insignificant based upon analysis of Oat3-selective substrates in knock-outs (7, 38, 39). Although Oat3 transport of mercury in vitro has been reported, it remains possible, although unlikely, that some of the observed protection was due to somewhat decreased Oat3 expression. The expression of other Slc22 family members is unchanged (40). Moreover, in vitro evidence suggests that Oat1 is the primary mediator of proximal tubular basolateral uptake of mercuric conjugates. On the other hand, several transporters, including multidrug resistance-associated proteins of the ABCC gene family, have been suggested to mediate the mercury excretion at the apical membrane of the proximal tubules. However, our previous analysis of ABCC gene family expression did not reveal significant alterations in the Oat1 knock-out kidneys (40).

In summary, in the study, we demonstrated that a single dose of HgCl₂ can cause acute kidney injury in both rats and mice, which is mediated mainly by injury to the proximal tubule. This injury is directly linked to the organic anion transporter Oat1 based on in vivo and in vitro studies. The fact that mercury-induced acute kidney injury is directly linked to Oat1 expression may be useful for developing biological protection against toxic effects exerted by mercury or by specific forms of mercury. Pharmacological modulation of the expression and/or function of Oat1 (such as the use of specific inhibitors) might be an effective therapeutic strategy for reducing kidney injury due to mercury.

Oat1/Slc22a6 Mediates Mercury Kidney Injury
