Purpose: Postoperative urinary retention (POUR) is one of the most common complications following spinal anesthesia. Spinal anesthesia may influence urinary bladder function due to interruption of the micturition reflex. Urinary catheterization is the standard treatment of POUR. Urinary catheter insertion is an invasive procedure, which is associated with catheter-related infections, urethral trauma, and patient discomfort. The purpose of this study was to determine the effectiveness of intramuscular (IM) neostigmine to accelerate bladder emptying after spinal anesthesia.

Patients and methods: A total of 36 patients undergoing lower abdominal (except for pelvic, urologic, ano-rectal, and hernia surgery) and lower extremity surgery under spinal anesthesia were divided into two groups randomly (n=18), to either neostigmine (N) group or control (C) group. Neostigmine 0.5 mg (N group) or NaCl 0.9% (C group) was administered intramuscularly when Bromage score 0 and sensory level sacral two have been achieved. The time to first voiding after IM injection and the time to first voiding after spinal anesthesia were measured.

Results: The time to first voiding after IM injection was significantly faster (P≤0.05) in the N group than that in the C group, with median time as 40 minutes (20–70 minutes) and 75 minutes (55–135 minutes), respectively. Time to first voiding after spinal anesthesia was also significantly faster (P≤0.05) in the N group than that in the C group (mean of 280.8±66.6 minutes and 364.2±77.3 minutes, respectively).

Conclusion: IM neostigmine effectively accelerates bladder emptying after spinal anesthesia.

Keywords: neostigmine, postoperative urinary retention, bladder emptying, spinal anesthesia, anticholinesterase, neuraxial anesthesia

Introduction

Postoperative urinary retention (POUR) is a common complication after anesthesia and surgery; the incidence rate varies from 5% to 70%. Type of surgery, type of anesthesia, analgesics, anticholinergics, and comorbidities may predispose patients to development of POUR.1–4 POUR is one of the most common complications following spinal anesthesia. Spinal anesthesia may influence urinary bladder function due to interruption of the micturition reflex. The duration of these disturbances depends on both the potency and administered dose of local anesthetics.1,5,6

Kamphuis et al7 in their study concluded that spinal anesthesia with lidocaine and bupivacaine causes a clinically significant disturbance in bladder function. The urge to void disappears quickly after spinal injection of the local anesthetics. Similarly, a systematic review by Choi et al6 also concluded that neuraxial anesthesia/analgesia results

in transient detrusor dysfunction. The duration of dysfunction depends on the potency and dose of medication used.

Postoperative urine retention has been defined as the inability to void in the presence of a full bladder. Clinical examination and ultrasonographic assessment can be used to diagnose POUR. At least there were five different calculation methods to measure urinary bladder volume in real time. Catheterization is recommended if the patient is unable to void with a bladder volume > 600 mL detected by ultrasound. Urinary catheter insertion is an invasive procedure, which is associated with catheter-related infections, urethral trauma, and patient discomfort.1,7–9

There are various medications for treatment of POUR, including cholinergic agents, anticholinesterase agents, alpha-blockers, sedatives and prostaglandin.10,11 Neostigmine is an acetylcholinesterase inhibitor or anticholinesterase agent. It causes accumulation of acetylcholine around the cholinergic nerve terminals. Urinary bladder contraction is critically dependent on acetylcholine-induced stimulation of contractile muscarinic receptors on the smooth muscle (detrusor) of the urinary bladder.11–13

Bałkota et al14 analyzed the efficacy of the intramuscularly administered neostigmine in the prevention of POUR in the patients who underwent orthopedic procedures under spinal anesthesia. However, the results were not statistically significant.

Through this research, we tried to determine the effectiveness of intramuscular (IM) 0.5 mg neostigmine to accelerate bladder emptying after spinal anesthesia.

Patients and methods

Patients

This is an experimental study with a double-blind, randomized, controlled trial design. A total of 36 patients aged 18–50 years with American Society of Anesthesiologists (ASA) physical status I–II undergoing lower abdominal (except for pelvic, urologic, anorectal, and hernia surgery) and lower extremity surgery under spinal anesthesia in the central operating theater at Sanglah Hospital (Joint Commission International – Accredited) from October through December 2017 were admitted to the study. Patients were not admitted to the study if any the following criteria were present: patient refusal, contraindications using local anesthetics, contraindications to neostigmine, local infection at the site of injection, urinary tract symptoms (frequency, incontinence, enuresis, nocturia, hesitancy, urgency, weak stream, dysuria, and inability to empty the bladder fully), surgical duration >2 hours, and intraoperative blood loss >200 mL. After the subjects were assessed for eligibility, random assignment was done using the block randomization method.

Procedures

Patients were allowed to drink clear fluid up to 200 mL until 2 hours before induction of anesthesia. All patients were asked to urinate before transfer to the central operating theater. Intravenous access was obtained, and ringer lactate infusion was started in the preparation room of central operating theater. In the operating room, standard monitoring (electrocardiography, noninvasive blood pressure, and pulse oximetry) was installed and the subjects received oxygen supplementation 2 L/min through a nasal cannula. Spinal anesthesia was done using Quincke-type needle G27 using 0.5% hyperbaric bupivacaine. The height of the block based on skin dermatome was performed by the pinprick test.

After the surgery was finished, in the postoperative care unit, the subjects either received 0.5 mg IM neostigmine (N group) or IM NaCl 0.9% (C group). IM injection was performed when Bromage score (motor block assessment) 0 was achieved and height of the sensory block reached a level of S2 dermatome. Urinary bladder ultrasound was performed hourly until spontaneous micturition occurred. If POUR occurred (inability to void with a bladder volume >600 mL detected by ultrasound), then they will be catheterized. The prolate ellipsoid method was used to measure urinary bladder volume based on the formula volume=length×width×height×0.52 on a two-dimensional image.

Local anesthetic dose for spinal anesthesia, level of sensory block, surgical duration, the amount of intraoperative fluid, urinary bladder volume before IM injection, time to first voiding after IM injection, time to first voiding after spinal anesthesia, volume of urine excreted, postvoid residual volume, and patients who needed urinary catheterization were measured.

Statistical analyses

All statistical analyses were conducted using SPSS for Windows (IBM Corporation, Armonk, NY, USA) software version 20. Data were assessed for their conformance to the normal distribution using the Shapiro–Wilks test. Numerical variables were expressed as mean±SD or median (minimum–maximum), and categorical variables were expressed as frequency (%). Independent t-test was used to compare mean values if data distribution was normal, or nonparametric Mann–Whitney U test was used if data were not distributed normally. Categorical variables were assessed using χ² or
Fischer’s exact test. Results were considered as significant at P<0.05.

Ethics statements
This research was approved by research ethics committee of Faculty of Medicine Udayana University and Sanglah Hospital. All subjects gave written informed consent and were fully informed of the procedures prior to participation in the studies.

Results
There were no significant differences (P>0.05) in both groups in terms of sex, age, body mass index, and ASA physical status (Table 1). As given in Table 2, local anesthetic dose for spinal anesthesia, level of sensory block, surgical duration, and the amount of intraoperative fluid were not significantly different between two groups (P>0.05).

Postoperatively (Table 3), urinary bladder volume before IM injection was not significantly different between two groups (P>0.05). Time to first voiding after IM injection was significantly faster (P≤0.05) in the N group than that in the C group, with median time as 40 minutes (20–70 minutes) and 75 minutes (55–135 minutes), respectively. Time to first voiding after spinal anesthesia was also significantly faster (P≤0.05) in the N group than that in the C group (mean of 280.8±66.6 minutes and 364.2±77.3 minutes, respectively). Volume of urine excreted was higher in the C group than that in the N group with median volume as 322 mL (150–400 mL) and 230 mL (150–400 mL), respectively, but was not significantly different (P>0.05). Postvoid residual volume was significantly lower (P≤0.05) in the N group than that in the C group (mean of 112.5±17.8 minutes and 190±23.3 minutes, respectively). One (5.6%) subject in the N group and three (16.7%) subjects in the C group were catheterized due to urinary retention but did not differ significantly (P>0.05).

Table 1 Subject characteristics

| Characteristics      | Groups |     | P-value |
|----------------------|--------|-----|---------|
|                      | N (n=18) | C (n=18) |         |
| Sex                  |         |     |         |

Discussion
Spinal anesthesia is a common anesthesia technique used in patients undergoing abdominal and lower extremity surgery. POUR is one of the most common complications following spinal anesthesia. Intrathecal local anesthetics inhibit the transmission of the afferent and efferent action potentials on the nervous fibers of the sacral spinal cord segments (S2–S4) from and to the bladder. The feeling of urgency to void disappears 30–60 seconds after spinal anesthesia, but a dull sensation of tension on maximal filling of the bladder persists. Inhibition of the afferent nerve fibers’ transmission from the bladder to the micturition center in the brain leads to bladder analgesia. The detrusor contraction is completely abolished 2–5 minutes after the intrathecal local anesthetics injection. The recovery of detrusor muscle activity depends on the duration of sensory block above the S2 and S3 sacral segments.<sup>1,5,6</sup>

Neostigmine is an acetylcholinesterase inhibitor that causes accumulation of acetylcholine around the cholinergic nerve terminals. It causes concentration-dependent contractions in rat urinary bladder. Acetylcholine will stimulate contractile muscarinic receptors on the smooth muscle (detrusor) of the urinary bladder and lead to urinary bladder contraction. Prolonged duration of acetylcholine in the receptor gives rise to stronger smooth muscle contraction.<sup>11–13</sup>

The function of the bladder is regulated by an interaction between the somatic, parasympathetic and sympathetic nervous systems. Parasympathetic nervous system provides the major excitatory innervation of the detrusor muscle. Stimulation of postsynaptic muscarinic receptors M2 and M3 is considered as the most important, although many receptor systems and mediators are responsible for detrusor contraction. In terms of quantity, the M2 subtype dominates over the...
M3 subtype in the detrusor, but M3 subtype was confirmed to be the major contraction receptor.\textsuperscript{15,16}

In our study, IM neostigmine effectively accelerates bladder emptying. Time to first voiding after IM injection and time to first voiding after spinal anesthesia were significantly faster in the N group. The postvoid residual volume was also significantly lower in the N group, which indicates that neostigmine improves muscle contraction after spinal anesthesia. However, the effectiveness of IM neostigmine to accelerate bladder emptying was not followed by significant reduction in incidence of POUR and urinary catheterization in the N group. One (5.6%) subject in the N group and three (16.7%) subjects in C group were catheterized due to urinary retention. This phenomenon could be caused by patient’s age and type of surgery in our study. Lower abdominal (except for pelvic, urologic, anorectal, and hernia surgery) and lower extremity surgery were considered as of low-risk for POUR. Incidence of POUR has been shown to increase with age, and the risk increases at age $\geq$50 years. Hence, effectiveness of IM neostigmine to accelerate bladder emptying might be masked by low incidence rate of POUR in our study. Further research with large sample and high-risk surgery is needed to confirm this presumption.

**Conclusion**

This study indicated that IM neostigmine effectively accelerates bladder emptying after spinal anesthesia but did not decrease the incidence of POUR and frequency of urinary bladder catheterization in patients undergoing lower abdominal (except for pelvic, urologic, anorectal, and hernia surgery) and lower extremity surgery under spinal anesthesia.
