T-optimal designs for multi-factor polynomial regression models via a semidefinite relaxation method

Yuguang Yue · Lieven Vandenberghe · Weng Kee Wong

Received: date / Accepted: date

Abstract We consider T-optimal experiment design problems for discriminating multi-factor polynomial regression models where the design space is defined by polynomial inequalities and the regression parameters are constrained to given convex sets. Our proposed optimality criterion is formulated as a convex optimization problem with a moment cone constraint. When the regression models have one factor, an exact semidefinite representation of the moment cone constraint can be applied to obtain an equivalent semidefinite program. When there are two or more factors in the models, we apply a moment relaxation technique and approximate the moment cone constraint by a hierarchy of semidefinite-representable outer approximations. When the relaxation hierarchy converges, an optimal discrimination design can be recovered from the optimal moment matrix, and its optimality is confirmed by an equivalence theorem. The methodology is illustrated with several examples.

find a design to collect data optimally to identify the most appropriate model. Once this task is accomplished, one proceeds to the next phase of the scientific investigation, which may be to estimate parameters in the selected model or use the model for making statistical inferences, such as predicting values of the responses at selected regions. Alternatively, one performs model diagnostics after the data are collected and evaluates whether the model assumptions are valid. We propose a new method for finding an optimal design to discriminate among several multi-factor polynomial regression models defined on a user-selected compact multi-factor design space \( X \) and show that it is straightforward to implement our strategy.

Atkinson and Fedorov (1975a,b) were among the first to formulate a statistical framework for finding an optimal discrimination design when the class of plausible models is defined on a user-defined space. The response variable is univariate and continuous, and all errors are assumed to be normally distributed, each with mean zero and equal variance. This has been the traditional setup for finding optimal discrimination designs until recently where errors are allowed to be non-normally distributed.

Our work assumes all models of interest are polynomial models where the cone of possible moment matrices may be represented as an exact semidefinite representation. This is possible when the polynomial model has one factor, but not for general polynomial models (Shohat and Tamarkin 1943; Scheiderer 2018). For the latter situation, we use the moment-sum-of-square hierarchy to approximate the moment cone.

Our method has several advantages over current methods for discriminating several models. First, we do not need to assume a known true (null) model among the plausible models. Until recently, this assumption is required in the optimal discrimination design and is a frequent critique of the setup, see for example, Fedorov and Malyutov (1972), Atkinson and Cox (1974), Atkinson and Fedorov (1975a,b) and Duarte et al. (2015); our setup permits possible values of the parameters to belong to any convex sets \( \Theta_j \) and not singleton sets. Second, unlike some of the state-of-the-art algorithms that require the design space be discretized for finding an optimal design (Yang et al. 2013), our method does not require us to replace a continuous design space by a set of candidate design points. This is an important consideration because for high dimensional problems where we have several factors, methods based on discretizing the search space are likely to be slow. A third advantage of our method is that we do not require the number of support points in the optimal design to be specified in advance. This is in contrast to several mathematical programming approaches, such as those in Duarte et al. (2015), where the semi-infinite programming algorithm requires a pre-selected number of design points to start with. Fourth, our approach is flexible in that the design space can be defined by polynomial inequalities to more realistically capture the physical or cost constraints of the design problem. For example in mixture models, where the mean response is commonly modeled using Scheffé’s, Becker’s or Kasatkin’s polynomial models (Wong et al. 2015), our framework can directly incorporate polynomial constraints on the design space.
Section 2 describes the statistical background of experiment designs. Section 3 provides the formulation of the optimal discrimination design problem along with the exact representation of a special case, and introduces the hierarchy moment relaxation algorithm that includes moment relaxation theory, equivalence theorem and the solution extraction method. Section 4 shows the detailed steps of our algorithms. In Section 5, we provide six examples, some of which are specially selected to demonstrate that the algorithm generates the same theoretical optimal designs in the literature. Section 6 provides a summary and a brief discussion on some of the unpredictable properties of the optimal discrimination designs, some limitations of our approach and future direction of our work. In the appendix, we provide a sample Matlab code that we used to generate one of the optimal discrimination designs in this paper.

2 Background

An experimental design is optimal if it optimizes a given criterion over the set of all designs on the design space. The most common design criterion is D-optimality that seeks to minimize the determinant of the covariance matrix of the estimated parameters [Fedorov 1972; Waterhouse et al. 2009; Duarte et al. 2018]. Much less attention has been given to finding an optimal design that discriminates among competing models. The theoretical framework for experimental design for model discrimination using T-optimality was established in a series of papers by Fedorov and Malyutov (1972); Atkinson and Cox (1974) and Atkinson and Fedorov (1975a,b). The typical setup assumes that we want to discriminate between two parametric models, one of which is a fully known parameterized ‘true model’ and the other is a ‘test model’ with a known mean function apart for the values of the parameters. The T-optimal design maximizes the lack of fit sum of squares for the second model by maximizing the minimal lack of fit sum of squares arising from a set of plausible values of the unknown parameters [Fedorov and Malyutov 1972; Atkinson and Fedorov 1975a].

Additional theoretical developments can be found in De Leon and Atkinson (1991); Dette (1994); Fedorov and Hackl (2012); Wiens (2009) and, Dette and Titoff (2009). Uciński and Bogacka (2005) proposed a generalized criterion for multi-response model and Carlos Monteiro Ponce de Leon (1993) gave a criterion for discriminating between binary outcome models. T-optimality has been applied to discriminate among polynomial models [Dette et al. 2012], Fourier regression models [Dette et al. 2003], Michaelis-Menten kinetic models [Atkinson 2012] and dynamic systems described by sets of ordinary differential equations [Uciński 2004]. When errors are not normally distributed, KL-optimality is used instead of T-optimality to discriminate among models; see López-Fidalgo et al. (2007), among others. Most recently, Dette et al. (2018) proposed an interesting and relatively easy method to find an optimal design to discriminate among semi-parametric models.
In general, finding T-optimal designs is a challenging problem especially when multiple models are involved because the design criterion is not differentiable and the structure of the optimization problem has two or more layers of nested optimization. Consequently, formulae for T-optimal designs are only available for simple optimal discrimination design problems. Several algorithms have been proposed to specially find a T-optimal design. Some examples are Wynn (1970); Fedorov (1971); Fedorov and Malyutov (1972); Atkinson and Fedorov (1975a,b) where they sequentially add one or more points specially selected to the current design. Unrelated to previous methods, Duarte et al. (2015) proposed using semi-infinite programming to solve an optimal discrimination design problem.

We focus on finding an optimal discrimination design under a concave criterion when we have a polynomial regression model with several factors on a compact, possibly non-convex, design space $\mathcal{X}$. We denote the mean response for each of the $K$ possibilities by $\eta_1(x), \ldots, \eta_K(x)$ and let $f(x)$ be the $l \times 1$-vector of basis monomial functions of regressors with input factor $x$. The method is not restricted to monomials and can be readily extended to other polynomial basis functions.

The mean response function for each of the $K$ models is
$$\eta_j(x) = \theta_j^T f(x) + \epsilon_j, \quad j = 1, \ldots, K,$$
where $\theta_j^T = [\theta_{j1}, \ldots, \theta_{jl}]^T$ is a partially unknown parameter vector and $\epsilon_1, \ldots, \epsilon_K$ are independent random noises, each with standard Gaussian distribution with zero mean and unit variance. We assume that for the $j$th model, there is a known set $\Theta_j$ that contains all the possible values of the parameter vector $\theta_j, j = 1, \ldots, K$, and all such sets are distinguishable. The constraint $\theta_j \in \Theta_j$ may include the constraint that certain coefficients of $\theta_j$ are zero, i.e., the model $j$ does not involve certain basis functions in $f(x)$. This allows us to simplify our notation and use the same vector of basis functions $f(x)$ for each model.

Suppose we have resources to take $N$ observations for our study and $\xi$ is a design that takes $p_i$ proportion of the $N$ observations at the design point $x_i \in \mathcal{X}, i = 1, \ldots, m$. We call such a design a continuous design and represent it by
$$\xi = \begin{pmatrix} x_1 & \cdots & x_m \\ p_1 & \cdots & p_m \end{pmatrix}.$$  

The first row displays the support points of the design and the second row displays the proportion of observations to be taken at each of the support points. Clearly $p_1 + \ldots + p_m = 1$. In practice, the continuous design is implemented by first rounding each $Np_i$ to an integer subject to the constraint that they sum to $N$. The advantages of working with continuous designs are that, when the criterion is concave, a unified theory exists for finding optimal continuous designs and there are algorithms for finding a variety of optimal designs. Further, there are equivalence theorems to confirm optimality of a design and simple analytical tools for checking proximity of a design to the optimum without knowing the optimum.
3 Solution via semidefinite optimization

3.1 Reformulation of the design problem

A T-optimal design maximizes the minimal squared distance between the mean responses from two possible polynomial models. Each of our regression models is defined on $X$ and can be represented as

$$
\eta_j(x) = \theta_j^T f(x) + \epsilon_j, \quad j = 1, 2, \ldots, K
$$

where $\theta_j \in \Theta$, $\epsilon_j \sim N(0, \sigma^2)$, and $f(x)$ is $l$-dimensional and contains the $l = C_n^{n+d} = (n+d)!/(n!d!)$ monomials of degree $d$ or less in the $n$ factors $x$.

We recall the $l \times l$ matrix $M(\xi) = \int_X f(x)f(x)^T d\xi$ is the moment matrix of the design $\xi$ and $M(\xi)$ is a linear function of $\xi$. In what is to follow, we write $M(\xi)$ as $M$ and optimize it as a variable directly under a given criterion. The sought design is then recovered from the optimal $M$.

Given a design $\xi$, let $\Delta_{jk}(M)$ be the non-centrality parameter for the pair of models $j$ and $k$ defined by

$$
\Delta_{jk}(M) = \inf_{\theta_j \in \Theta_j, \theta_k \in \Theta_k} \int_X (\theta_j^T f(x) - \theta_k^T f(x))^2 d\xi
$$

$$
= \inf_{\theta_j \in \Theta_j, \theta_k \in \Theta_k} (\theta_k - \theta_j)^T M(\theta_k - \theta_j).
$$

We note that the function $\Delta_{jk}(M)$ is concave in $M$ because it is the point-wise infimum of a family of linear functions of $M$ \cite{BoydVandenberghe2004}. The quantity $\Delta_{jk}$ represents the infimum of the squared distance between the mean responses from model $j$ and model $k$ over all possible choices of the parameters in $\Theta_j$ and $\Theta_k$. If we wish to discriminate between model $j$ and model $k$ only, the T-optimal design maximizes $\Delta_{jk}(M)$ over all designs $\xi$.

If there are $K > 2$ models to discriminate, there are $K(K-1)/2$ such criteria, one for each pair of models. These are generalizations of the non-centrality parameters discussed in \cite{AtkinsonFedorov1975}, where they noted that T-optimality applies to nested models only when there are constraints placed on the model parameters; otherwise the non-centrality parameter is zero and the T-optimality criterion is not appropriate. \cite{AtkinsonFedorov1975} provides an illustrative example of such a situation; see also the introduction in \cite{DetteTitoff2009} where they provided a motivation for T-optimality.

Our optimal discrimination design problem involving several models can be reduced to a single-objective optimization problem by considering

$$
\max_{\xi} \min_{j > k} \Delta_{jk}(M)
$$

subject to $M \in \mathcal{M}$

(1)
where \( \mathcal{M} \) is the set of possible moment matrices \( M \). Alternatively, we can maximize a weighted sum, as in
\[
\maximize_{\xi} \sum_{j > k} w_{jk} \Delta_{jk}(M)
\]
subject to \( M \in \mathcal{M} \),

(2)

with nonnegative weights \( w_{jk} \). Let
\[
\delta_\Theta(x) = \begin{cases} 
0 & x \in \Theta \\
+\infty & \text{otherwise}
\end{cases}
\]
be the indicator function of the closed and convex set \( \Theta \) with a nonempty relative interior. We then use convex duality theory and derive an alternative expression for \( \Delta_{jk}(M) \). The function \( \Delta_{jk}(M) \) is the optimal value of the convex optimization problem
\[
\minimize_{u, \theta_j, \theta_k} u^T M u + \delta_{\Theta_j}(\theta_j) + \delta_{\Theta_k}(\theta_k)
\]
subject to \( u = \theta_j - \theta_k \)

(3)

with variables \( u, \theta_j, \theta_k \). The Lagrangian for this problem is
\[
L(u, \theta_j, \theta_k) = u^T M u + \delta_{\Theta_j}(\theta_j) + \delta_{\Theta_k}(\theta_k) + z^T (u - \theta_j + \theta_k)
\]
and the dual function is the unconstrained infimum of \( L \) over \( u, \theta_j, \theta_k \):
\[
\inf_{u, \theta_j, \theta_k} L(u, \theta_j, \theta_k) = \inf_u (u^T M u + z^T u) + \inf_{\theta_j} (\delta_{\Theta_j}(\theta_j) - z^T \theta_j) + \inf_{\theta_k} (\delta_{\Theta_k}(\theta_k) + z^T \theta_k)
\]
\[
= -\frac{1}{4} z^T M^{-1} z - \delta_{\Theta_j}^*(z) - \delta_{\Theta_k}^*(-z),
\]
where \( \delta_{\Theta}^*(x) \) is the value of the support function of the set \( \Theta \) at the point \( x \). We recall from [Rockafellar, 1970] that the support function of a set \( C \) is defined as the conjugate of the indicator function, i.e.
\[
\delta_C^*(y) = \sup_x (y^T x - \delta_C(x)) = \sup_{x \in C} (y^T x).
\]

In the minimization of the Lagrangian we have assumed that \( M \) is invertible. If \( M \) is not invertible, the first term \( z^T M^{-1} z \) in the expression for the dual function should be interpreted as \( +\infty \) if \( z \) is not in the range of \( M \), and as \( z^T M^+ z \) otherwise, where \( M^+ \) is the pseudo-inverse of \( M \).

Accordingly, the dual problem is
\[
\maximize_z -\frac{1}{4} z^T M^+ z - \delta_{\Theta_j}^*(z) - \delta_{\Theta_k}^*(-z)
\]

(4)
with variable \( z \), which can be further rewritten as

\[
\begin{align*}
\text{maximize} & \quad -t - \delta_{\Theta_j}^*(z) - \delta_{\Theta_k}^*(-z) \\
\text{subject to} & \quad \begin{bmatrix} M & z \\ z^T & 4t \end{bmatrix} \succeq 0,
\end{align*}
\]

(5)

with variables \( t \) and \( z \). From convex duality theory, the problems (3) and (5) have the same optimal values. It follows that for fixed \( M \) the optimal value of (5) is also \( \Delta_{jk}(M) \). However, since the constraint is convex in \( M \), we can jointly optimize over \( M \), \( t \), and \( z \) to maximize \( \Delta_{jk}(M) \). This observation allows us to write problem (1) as

\[
\begin{align*}
\text{maximize} & \quad M, t, z_{jk} \\
\text{minimize} & \quad j > k \sum_{j > k} w_{jk} t_{jk} - \delta_{\Theta_j}^*(z_{jk}) - \delta_{\Theta_k}^*(-z_{jk}) \\
\text{subject to} & \quad \begin{bmatrix} M & z_{jk} \\ z_{jk}^T & 4t_{jk} \end{bmatrix} \succeq 0, \quad j > k \\
M \in \mathcal{M},
\end{align*}
\]

(6)

with variables \( M \), \( t_{jk} \) and \( z_{jk} \) for \( j < k \). A similar reformulation for problem (2) leads to

\[
\begin{align*}
\text{maximize} & \quad M, t, z_{jk} \\
\text{minimize} & \quad j > k \sum_{j > k} w_{jk} t_{jk} - \delta_{\Theta_j}^*(z_{jk}) - \delta_{\Theta_k}^*(-z_{jk}) \\
\text{subject to} & \quad \begin{bmatrix} M & z_{jk} \\ z_{jk}^T & 4t_{jk} \end{bmatrix} \succeq 0, \quad j > k \\
M \in \mathcal{M},
\end{align*}
\]

(7)

In practice, the sets \( \Theta_j, j = 1, \ldots, K \) are often simple, and their support functions are easy to compute. The main difficulty in solving (6) and (7) is in the moment constraint \( M \in \mathcal{M} \), which is a set that is hard to characterize efficiently even though it is a convex set. The set \( M \in \mathcal{M} \) can only be described analytically in a few special cases. For example, for univariate polynomials, the set \( \mathcal{M} \) can be represented exactly by a set of semidefinite constraints, using classical results from moment theory. Consider, for example, \( X = [0, 1] \) and \( f(x) = (1, x, \ldots, x^d) \), the set \( \mathcal{M} \) is defined by two linear matrix inequalities

\[
M = \begin{bmatrix} 1 & c_1 & c_2 & \cdots & c_d \\ c_1 & c_2 & c_3 & \cdots & c_{d+1} \\ c_3 & c_4 & c_5 & \cdots & c_{d+2} \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ c_{d-1} & c_d & c_{d+1} & \cdots & c_{2d-1} \end{bmatrix} \succeq 0
\]

and

\[
\begin{bmatrix} c_1 - c_2 & c_2 - c_3 & \cdots & c_d - c_{d+1} \\ c_2 - c_3 & c_3 - c_4 & \cdots & c_{d+1} - c_{d+2} \\ \vdots & \vdots & \ddots & \vdots \\ c_{d-1} - c_d & c_d + 1 & \cdots & c_{2d-1} - c_{2d} \end{bmatrix} \succeq 0.
\]
see, for example, Theorem 1.1 in Karlin and Studden (1966). In other cases, one can resort to approximating $\mathcal{M}$ by outer semidefinite approximations using techniques that have been developed recently in semidefinite programming methods for polynomial optimization, see for example, Lasserre (2001, 2015). This is explained in more detail in the next section.

3.2 Moment relaxation

Except in special cases like the one discussed above, Scheiderer (2018) has proved that the moment cone is not semidefinite representable, i.e. it cannot be expressed as the projection of a linear section of the cone of positive semidefinite matrices. An important tool commonly used to find optimal designs for polynomial regression is the theory of moment relaxation introduced by Lasserre (2001, 2009). In what is to follow, we give a brief heuristic introduction of this concept. In particular, we illustrate how the complicated moment matrix constraint can be represented as semidefinite constraints after we introduce some additional and necessary notation.

3.2.1 Truncated moment cone

Let $x^\alpha := x_1^{\alpha_1} \cdots x_n^{\alpha_n}$ be a monomial with $\alpha = (\alpha_1, \cdots, \alpha_n) \in \mathbb{N}^n$ and let $\mathcal{M}_+(\mathcal{X})$ be the set of nonnegative Borel measures supported on $\mathcal{X}$.

Given a nonnegative Borel measure $\xi$ with support on $\mathcal{X}$,

$$y_\alpha = \int_{\mathcal{X}} x^\alpha d\xi$$  \hspace{1cm} (8)

is the moment of order $\alpha$ of $\xi$. Let $y = (y_\alpha)_{\alpha \in \mathbb{N}^n}$ be the moment sequence of $\xi$ and for a pre-selected positive integer $d$, let $y_d = (y_\alpha)_{|\alpha| \leq 2d}$ be the truncated sequence that includes the elements corresponding to $|\alpha| \leq 2d$, where $|\alpha| = \sum_{i=1}^n \alpha_i$. For brevity, we write $y_d$ simply as $y$ when the truncated degree is 2, and add a special subscript when truncated degree is different. The moment matrix of a polynomial regression model with $n$ factors in $\mathcal{X}$ and highest degree $d$ is a one to one map to the set

$$\mathbb{C}_{2d}(\mathcal{X}) := \{ y \in \mathbb{R}^q : \exists \xi \in \mathcal{M}_+(\mathcal{X}) \text{ s.t. } y_\alpha = \int_{\mathcal{X}} x^\alpha d\xi \},$$

with $q = C_n^{n+2d}$, which is a set of moment sequences. Here is a simple example. Suppose we have $n = 2$ factors with highest degree $d = 1$. The moment sequence is a vector with $C_2^1 = 6$ elements and the moment matrix is

$$M(\xi) = \begin{pmatrix}
    y(0,0) & y(1,0) & y(0,1) \\
    y(1,0) & y(2,0) & y(1,1) \\
    y(0,1) & y(1,1) & y(0,2)
\end{pmatrix}. $$
Notice that $M(\xi)$ is the same as $M$ in section 3.1, where we now denote it as a function of $\xi$ to emphasize its relationship with designs. The matrix is symmetric and is determined by the six elements in the vector $y = [y_{(0,0)}, y_{(1,0)}, y_{(0,1)}, y_{(2,0)}, y_{(1,1)}, y_{(0,2)}]$. Therefore, each moment matrix is uniquely defined by a moment sequence, and we denote it as $M_d(y)$, where $d$ is the highest degree of factors.

### 3.2.2 Semidefinite approximations of moment cone

We constrain the design space $X$ by a set of inequalities constraints to use the hierarchy approximation method. Let $g_i(x)$ be given polynomials of degree $d_i$ and let

$$X := \{x \in \mathbb{R}^n : g_i(x) \geq 0, i = 1, \cdots, L\}.$$

Given $d$, we define a localizing matrix for a given multi-factor polynomial $f(x) = \sum_{|\alpha| \leq 2s} f_\alpha x^\alpha$ of degree $2s$ by a sequence $y_s = (y_{\alpha})_{|\alpha| \leq (2d+2s)}$. The entry correspond to $(\alpha, \beta)$ of this localizing matrix $M_d(fy_s)$ has the form

$$\sum_{|\gamma| \leq 2s} f_\gamma y_{\gamma + \alpha + \beta}.$$

By Putinar’s theorem (Lasserre 2009), a moment cone can be approximated by a hierarchy of semidefinite cones. Given $g_i$ as described above, let $v_i = [d_i/2], 1 \leq i \leq L, q = C_n^{\tau+2d}, v = C_n^{\tau+2(d+\tau)}$ and $\tau \in \mathbb{N}$ is a pre-selected relaxation order. Define

$$C_{2d+(d+\tau)}^{SDP}(X) := \{y \in \mathbb{R}^q : \exists y_\tau \in \mathbb{R}^n \text{ s.t. } (y_\tau)_{|\alpha| \leq 2d} = y, M_{d+\tau}(y_\tau) \succeq 0, M_{d+\tau-v_i}(g_i y_\tau) \succeq 0, \forall i\},$$

where $y_\tau = (y_{\alpha})_{|\alpha| \leq (2d+2\tau)}$ and $(y_\tau)_{|\alpha| \leq 2d}$ is a vector composed of the elements in $y_\tau$ corresponding to $|\alpha| \leq 2d$. Because $C_{2d}(X) \subseteq C_{2(d+\tau)}^{SDP}(X)$, this approach is called an outer approximation. By De Castro et al. (2017), $C_{2d}(X) \subseteq \cdots \subseteq C_{2(d+1)}^{SDP}(X) \subseteq C_{2d}^{SDP}(X)$ and the hierarchy converges, which means that $C_{2d}(X) = \bigcap_{d=0}^{\infty} C_{2(d+\tau)}^{SDP}(X)$. In what is to follow, we now use this fact and develop a semidefinite programming approximation scheme for the moment cone constraint problem. First rewrite our optimization problem as

$$\begin{aligned}
\text{maximize} & \quad \min_{j > k} (-t_{jk}) - \delta_{\Theta_j}(z_{jk}) - \delta_{\Theta_k}(-z_{jk}) \\
\text{subject to} & \quad M_d(y) \begin{bmatrix} z_{jk} \\ z_{jk}' \\ 4t_{jk} \end{bmatrix} \succeq 0, \quad j > k \\
& \quad y \in C_{2d}(X), \quad y_0 = 1.
\end{aligned}$$

By Theorem 4.3 in De Castro et al. (2017), constraint (10) can be approximated by a series of semidefinite constraints defined as (9). When the relaxation order $\tau \to \infty$, the optimization problem (10) is equivalent to
maximize \[ y_{jk}, z_{jk} \] subject to \[
\begin{bmatrix}
M_d(y) z_{jk} \\
\frac{z_{jk}^T}{4t_{jk}}
\end{bmatrix} \succeq 0, \quad j > k
\]
\[ y \in C^{\text{SDP}}_{2(d+\tau)}(X), \quad y_0 = 1, \]
which is a semidefinite programming problem with respect to $y$.

In practice, it may not be clear whether a certain relaxation has achieved convergence or not. This is especially so in high-dimensional problems, where it may be hard to discern whether the current relaxation is enough or a still higher relaxation is needed. In the latter case, greater computational effort is required to handle the additional variables and the larger moment matrix. When the criterion is convex, we resort to an equivalence theorem based on the duality theorem, to check whether a design is globally optimal or not. Subsection 3.4 provides details.

### 3.3 Solution extraction

The solution extraction problem is an $\mathcal{A}$-truncated $X$-Moment problem studied by Nie (2014). It concerns whether a given vector $y_\mathcal{A}$ admits an atomic measure $\mu$ in $X$. The problem can be proposed as one of finding an atomic measure $\mu$ that satisfies the constraints:

\[
\int_X x^\alpha \mu(dx) = y_\alpha \quad \forall \alpha \in \mathcal{A},
\]

where $\mathcal{A}$ is a finite set indicating the power set of the vector $y_\mathcal{A} = (y_\alpha)_{\alpha \in \mathcal{A}} \subset \mathbb{N}^n$.

From Nie (2014) and De Castro et al. (2017), the optimal design $\xi$ can be obtained by solving a hierarchy of $\mathcal{A}$-truncated $X$-Moment problems given by

\[
\begin{align*}
\text{minimize} \quad & \text{trace}(M_{d+r}(y_r)) \\
\text{subject to} \quad & M_{d+\tau}(y_r) \succeq 0, \\
& M_{d+r-v_i}(g_i y_r) \succeq 0, \quad i = 1, \ldots, L \\
& (y_r)_{|\alpha| \leq 2d} = y^*
\end{align*}
\]

where $v_i = \lceil d_i / 2 \rceil$, $y^*$ is the optimal value from (11) and $r$ is another user-selected relaxation order larger than $\tau$. We then increase the value of $r$ by one each time until a solution $y^*_r$ of (12) is found and it satisfies the rank condition

\[
\text{rank } M_{d+r}(y^*_r) = \text{rank } M_{d+r-v}(y^*_r)
\]

where $v = \max v_i$. Nie (2014) proved that when $y^*$ is a moment vector, the rank condition will definitely be satisfied when $r$ is large enough. After $y^*_r$ is obtained, we apply the methods in Henrion and Lasserre (2005) to extract the support points of the optimal design. We then calculate the weights using $y^*$ and support points based on (8).
3.4 Equivalence theorem

When the objective function to optimize is a convex function, an equivalence theorem may be used to check whether a given design is a global optimum. Each convex functional has a unique equivalence theorem which is based on the sensitivity function of the design under investigation. The sensitivity function of the design is the directional derivative of the convex functional in the direction of a degenerate design at the point \( x \) and evaluated at the design. The equivalence theorem states that if the design is optimal, its sensitivity function is non-positive throughout the design space with equality at its support points; otherwise, the design is not optimal among all designs on the given design space. When the design space is an interval with one factor, the sensitivity function is univariate and can be easily plotted on the design space for a visual appreciation. For example, when we have one factor and the vector of regression functions \( f(x) \) has \( l \) linearly independent components with homoscedastic errors, the equivalence theorem for \( D \)-optimality states the design \( \xi_D \) is \( D \)-optimal among all designs on \( \mathcal{X} \) if and only if
\[
\phi(x, \xi_D) - \Delta(\xi_D) \leq 0
\]
for \( x \in \mathcal{X} \), with equality at the support points of the \( T \)-optimal design.

To discriminate between two models using \( T \)-optimality, a direct calculation shows the criterion is proportional to the non-centrality parameter defined in subsection 3.1, which is
\[
\Phi(\xi) = \min_{\theta_{12}} \theta_{12}^T M(\xi) \theta_{12} = \theta_{12}^T M(\xi) \theta_{12}
\]
where \( \theta_{12} = \theta_1 - \theta_2 \) and \( M(\xi) = \int_{\mathcal{X}} f(x)f(x)^T d\xi \). Manifestly, the function \( \Phi(\xi) \) is a concave function of \( \xi \) over the set of all designs on \( \mathcal{X} \). If \( \xi^* \) is the optimal discrimination design and \( \xi' \) is the degenerate design at the point \( x \) near the optimum \( \xi^* \), we have
\[
\frac{\partial}{\partial \alpha} \{ \theta_{12}^T M[(1 - \alpha)\xi^* + \alpha\xi'] \theta_{12} \} |_{\alpha=0} \leq 0.
\]
This implies that
\[
\theta_{12}^T M(\xi^*) \theta_{12} - \Delta(\xi^*) \leq 0,
\]
where \( \Delta(\xi^*) = \theta_{12}^T M(\xi^*) \theta_{12} \) is the optimal value. If we let \( \phi(x, \xi^*) = \{ \eta_1(x, \theta_1) - \eta_2(x, \theta_2) \}^2 \), the equivalence theorem states that \( \xi^* \) is an optimal discrimination design if and only if
\[
\phi(x, \xi^*) - \Delta(\xi^*) \leq 0 \quad \text{for} \ x \in \mathcal{X},
\]
with equality at the support points of the \( T \)-optimal design.

For a design with several competing models, the equivalence theorem is a straightforward generalization of that for discriminating between two models [Atkinson and Fedorov 1975a]. If there is only one closest distance between different combinations of models and this occurs, say, between the null model and model \( k \), then the equivalence theorem becomes
\[
\phi_k(x, \xi^*) - \Delta(\xi^*) \leq 0
\]
where \( \phi_k(x, \xi^*) = (\eta_1(x) - \eta_k(x, \theta_{jk}^*))^2 \) with equality at the support points of the optimal design. For design problems where there are multiple points in the parameter space that achieve the smallest distance, see the more complicated equivalence theorem in Theorem 1 of [Atkinson and Fedorov (1975)].

We note that the design obtained by solving (11) and (12) with large enough relaxation orders \( \tau \) and \( r \) is a T-optimal design. The sensitivity function of the design provides us with an additional tool to confirm its optimality via the equivalence theorem. Since we only require the optimal moment matrix \( M(\xi^*) \) to obtain both \( \Delta(\xi^*) \) and \( \theta_{jk}^* \) to use the equivalence theorem, we can easily obtain information on whether the relaxation order \( \tau \) is big enough for the semidefinite relaxation mentioned in (11) to apply.

4 Algorithm

Our algorithm requires that the optimal discrimination design problem is properly formulated as a convex optimization problem. The proposed algorithm has three major steps: i). Solve the relaxed SDP problem in (11); ii). Extract the optimal design from the optimal moment matrix obtained from step 1 and iii). Use the equivalence theorem to validate the optimality of the design. These steps are described below, along with a set of pseudo codes for the whole procedure in the summary table labeled 4. We remind the reader that Step 3 is desirable but not a necessary step.

---

**Step 1: RelaxedSDP**

**Input:** Relaxation order \( \tau \geq 0 \), \( \{\Theta_k, k = 1, \cdots, K\} \), \( \{g_i(x), i = 1, \cdots, L\} \), basis function \( f(x) \).  
**Solve** (11) using Gloptipoly3 package and SDP solvers.  
**Output:** Optimal matrix \( M^*(\xi) \) and optimal value \( t^* \).

**Step 2: Extraction**

**Input:** Relaxation order \( r > 0 \), \( M^*(\xi) \), \( \{g_i(x), i = 1, \cdots, L\} \), basis function \( f(x) \).  
**Solve** (12) using Gloptipoly3 package and SDP solvers.  
**Output:** Support points of optimal design \( (x_1, \cdots, x_m) \).

**Step 3: EquivalenceTheorem**

**Input:** \( M^*(\xi) \), \( \{\Theta_k, k = 1, \cdots, K\} \), \( \{g_i(x), i = 1, \cdots, L\} \)  
**Check if** (13) holds for every single point on design space \( \mathcal{X} \).  
**Output:** True (equivalence theorem is not violated) or False.
Summary 4: T-optimal Design using SDP relaxation

**Input:** \( \{\Theta_k, k = 1, \ldots, K\}, \{g_i(x), i = 1, \ldots, L\}, \text{basis function } f(x) \)

\( t^*_1 = \infty, \tau = 0 \)

**while** True **do**

\( M^*(\xi), t^*_\tau = \text{RelaxedSDP}(\tau, \Theta_k, g_i(x), f(x)) \)

If \( t^*_\tau = t^*_{\tau-1} \) then

Break

Else

\( \tau = \tau + 1 \)

End if

End while

\( r = \tau + 1 \)

**while** True **do**

If \( \text{Extraction}(r, M^*(\xi), \{g_i(x), i = 1, \ldots, L\}, f(x)) \text{ succeed} \) then

\( \xi^* = \text{Extraction}(r, M^*(\xi), \{g_i(x), i = 1, \ldots, m\}, f(x)) \)

Break

Else

\( r = r + 1 \)

End if

End while

Validation = \( \text{EquivalenceTheorem}(M^*(\xi), \{\Theta_k, k = 1, \ldots, K\}, \{g_i(x), i = 1, \ldots, L\}) \)

If Validation then

Return optimal design

End if

Output: Optimal design \( \xi^* \), optimal value \( t^* \)

5 Examples

We provide several examples to demonstrate our proposed methodology. Some of the examples are selected to show our algorithm provides the same T-optimal designs reported in the literature and others to show our methodology is more flexible or efficient than current methods.

Convex optimization has been studied for decades and has many modeling tools and solvers to solve convex optimization problems efficiently. There are two classes of optimization softwares, one class serves as modeling tools and the other serves as solvers. Several modeling tools for convex problems are available for academic use and they include CVX \cite{Grant2008}, YALMIP \cite{Lofberg2004}, CVXPY \cite{Diamond2016}, LMI Lab \cite{Gahinet1994}, ROME \cite{Goh2011} and AIMMS \cite{Bisschop2006}. Both CVX and YALMIP can directly call popular solvers for SDP and they include Mosek \cite{ApS2017}, SeDuMi \cite{Sturm1999}, SDPT3 \cite{Toh1999}, etc.

5.1 Numerical Examples

We now apply the moment relaxation method to solve T-optimal design problems for a variety of situations. All of the examples are modeled by GloptiPoly3 \cite{Henrion2009} and YALMIP, and solved by MOSEK 7 or SeDuMi 1.3 in the MATLAB 2014a environment. For each example, we list results in Table
including the dimension of the design space, i.e. the number of factors in the study, the optimal value of the design criterion, CPU time for solving the problem, number of unknown parameters in the problem, number of support points in the optimal discrimination design, the optimal design and the relaxation orders of $\tau$ and $r$. All results were obtained using a 16 GB RAM Intel Core i7 machine running 64 bits Mac OS operating system with 2.5 GHz.

We present six examples with various setups to illustrate flexibility of our approach and its advantages over current methods. Except for one case, all factors are restricted to the design interval $[-1, 1]$, in this case, the polynomial inequality constraints would be $g(x_i) = 1 - x_i^2, \forall i = 1, \cdots, n$. Our examples include incomplete polynomial models, different numbers of factors in the models up to 7 and discrimination among two or three polynomial models. Some examples do not require the null model be completely specified and allows for different levels of uncertainty for each unknown coefficient in the polynomial model.

The first two univariate examples are selected from Duarte et al. (2015), from which we observe that our algorithm is more computationally efficient. Example 3 concerns an optimal design discrimination problem for two models, where possible values for the coefficients in each model are confined to a user-specified region. Example 4 and Example 5 show different solvers may be more appropriate for different situations. Example 6 is an optimal design discrimination problem for three competing models. Notice that we have listed models as $\eta_1, \eta_2$ and $\eta_3$ but this numbering is arbitrary as there is little difference whether one model is labelled first or not.

**Example 1:** This problem has one factor and the two mean functions have degrees up to 2.

- $\eta_1 = 1 + x + x^2$
- $\eta_2 = \theta_{20} + \theta_{21}x$
- $X = [-1, 1], \Theta_2 \in [0, 4]^2$.

A direct application of our algorithm produced the same optimal design reported as Case (2) in Duarte et al. (2015) which was found by semi-infinite programming method. Their CPU time is much longer than the CPU time required for our algorithm to generate the design, which is displayed in the first row of Table 1. Both algorithms gave the same optimal value.

**Example 2:** This problem has one factor and the two mean functions have degrees up to 5.

- $\eta_1 = 1 + x + x^2 + x^3 + x^5$
- $\eta_2 = \theta_{20} + \theta_{21}x + \theta_{22}x^2 + \theta_{23}x^3$
- $X = [-1, 1], \Theta_2 \in [0, 4]^4$.

This example is Case (4) in Duarte et al. (2015) where they solved the problem using a semi-infinite programming approach by first searching among designs with a predetermined number of points. This number is usually taken
to be equal to the number of parameters in the model plus 1, which is 5 in this case. If the algorithm does not converge, the search expands to among designs supported at one more point. It is common that only a copy of such expansions is needed. For this example, they found two asymmetric supported at 5 points optimal designs and their sensitivity functions show they satisfy the equivalence theorem. Interestingly, our algorithm produced a 6-point symmetric design shown in the second row of Table 1. It is, numerically, a convex combination of the two asymmetric designs and it has the same optimality value as the ones found by Duarte et al. (2015). A major difference is that our algorithm produced the optimal design much more efficiently in that it only required about 1.1 sec of CPU time compared to their 335 seconds of CPU time required by the semi-infinite programming method. However, our algorithm only finds an optimal design and does not find another when the optimal designs are not unique. We note that $\eta_1$ has the missing term $x^4$ in its mean function and so it is an example of an incomplete polynomial model as discussed in Dette et al. (2012).

Example 3: This problem has two factors and the two mean functions have degrees up to 2. Both null and alternative model have unknown coefficients in the polynomial models.

$\eta_1 = \theta_{10} + \theta_{11} x_1 + \theta_{12} x_2 + \theta_{13} x_1^2$
$\eta_2 = \theta_{20} + \theta_{21} x_1 + \theta_{22} x_2 + \theta_{23} x_1 x_2 + \theta_{24} x_2^2 + \theta_{25} x_1 x_2$
$X = [0, 4] \times [-1, 1], \theta_1 \in [0, 4]^4, \theta_2 \in [0, 2]^4 \times [1, 4]^2.$

Unlike the first two examples, the null model in this example is not fully specified. The parameter spaces of $\theta_{24}$ and $\theta_{25}$ do not include 0 so that the two models are not identical; otherwise, the two models are indistinguishable. This example also shows the flexibility of our methodology. One of the design spaces is no longer $[-1, 1]$ and the parameter spaces for the various model parameters are different, and neither of the models is fully specified. The left panel in Figure 1 shows the sensitivity function of the design found by GloptiPoly3. The optimal discrimination design and some characteristics of the design setup are reported in the 3rd row of Table 1.

Example 4: The problem has 3 factors and the null model is fully specified with some two factor interactions and the three factor interaction term.

$\eta_1 = 1 + x_1 + x_2 + x_3 + x_1^2 + x_2^2 + x_3^2 + x_1 x_2 x_3$
$\eta_2 = \theta_{20} + \theta_{21} x_1 + \theta_{22} x_2 + \theta_{23} x_3 + \theta_{24} x_1^2 + \theta_{25} x_2^2 + \theta_{26} x_3^2$
$X = [-1, 1]^3, \theta_2 \in [0, 4]^7.$

We solve this optimal discrimination design using SeDuMi. SeDuMi provides the solution quickly and precisely. When models have multiple factors, it is not easy to display and appreciate the properties of the sensitivity function of a design over the whole high dimensional design space. One option is to discretize the design space into a set of fine grid points and number them. We then order each index on the horizontal and plot the sensitivity function.
versus the ordered indices to confirm whether the number of peaks is equal to the number of support points in the generated design and the peaks correspond to the indices that match the support points of the design. We employ such a strategy to check optimality in this and other examples with multiple factors. The plot is shown on right panel in Figure 1. Another option is to order the points in a factorial order used in Fedorov and Leonov (2013) for a more specialized setup.

**Example 5:** This example has seven factors. The null model is fully specified with complete first and second order terms and all pairwise interaction terms. The alternative model has less factors and no interaction terms.

\begin{align*}
\eta_1 &= 1 + x_1 + \cdots + x_7 + x_1^2 + x_1x_2 + \cdots + x_6x_7 + x_7^2 \\
\eta_2 &= \theta_{20} + \theta_{21}x_1 + \theta_{22}x_2 + \theta_{23}x_3 + \theta_{24}x_4 + \theta_{25}x_5 + \theta_{26}x_6 + \theta_{27}x_1^2 + \theta_{28}x_2^2 + \\
&\quad + \theta_{29}x_3^2 + \theta_{2,10}x_4^2 \\
X &= [-1, 1]^7, \Theta_2 \in [0, 4]^{11}.
\end{align*}

In this example, the smallest rank relaxation does not work and we have to resort to using higher order relaxation, including SDP relaxation order \( \tau = 1 \) and extraction relaxation order \( r = 2 \). Mosek only takes several minutes to complete the extraction process and produce a solution. We observe that when the mean response is not symmetrically represented by the factors in the polynomial model, the distribution of the support points of the resulting optimal discrimination design is also asymmetric.
**Example 6:** This example has three models for discrimination. The null model is fully specified and has 3 factors up to order 2 with all pairwise interaction terms. The other 2 alternative models are additive; one has only first order terms and the other has up to second order terms.

\[
\begin{align*}
\eta_1 &= 1 + x_1 + x_2 + x_3 + x_1^2 + x_1x_2 + x_1x_3 + x_2^2 + x_2x_3 + x_3^2 \\
\eta_2 &= \theta_{20} + \theta_{21}x_1 + \theta_{22}x_2 + \theta_{23}x_3 \\
\eta_3 &= \theta_{30} + \theta_{31}x_1 + \theta_{32}x_2 + \theta_{33}x_3 + \theta_{34}x_1^2 + \theta_{35}x_2^2 + \theta_{36}x_3^2 \\
X &= [-1, 1]^3, \Theta_2 \in [1, 2]^4, \Theta_3 \in [1, 2]^7.
\end{align*}
\]

From this example, we also observe that our algorithm can not only solve the classical problem where the ‘true model’ has known parameters and the ‘test model’ has unknown parameters, but it can also discriminate two models with uncertain parameters. Specifically, this example with three possible models can be solved by introducing an auxiliary variable as the lower bound for three pairwise distances, and maximize over that auxiliary variable because we aim to maximize the minimal squared distance.

In this example, the optimal design has equal distances between \(\eta_1\), \(\eta_3\) and between \(\eta_2\) and \(\eta_3\). More specifically, under the optimal design, the distance between \(\eta_1\) and \(\eta_3\) is 4, while that between \(\eta_1\) and \(\eta_2\) is 13, and between \(\eta_2\) and \(\eta_3\) is 4. Noticing that the optimal \(\theta_{34}^* = \theta_{35}^* = \theta_{36}^* = 1\) when comparing models 2 and 3, this makes sense since between \(\eta_1\) and \(\eta_3\) their differences are in the second order interactions and the differences between \(\eta_2\) and \(\eta_3\) is only in the second order terms of the factors. Since there are no differences among those factors, it is reasonable that their interactions and their own second order terms have the same effects.

Figure 2 shows the directional derivative of the criterion evaluated at the optimal design. To show that there are exactly 8 design points in each plot, we discretize the space fairly sparse so that the design points can be observed clearly on the plots. In this case, we only sample 5 points uniformly from \(x_1, x_2\) and \(x_3\) to make the plot clear. However, when we ascertain optimality of a design using the equivalence theorem in practice, we need to discretize the space as dense as possible to verify that the sensitivity function has the same peak values at its support points. There are two plots because there are two competing pairs of models in this example with the same minimal distance. Accordingly, the equivalence theorem requires that we require two sensitivity plots to confirm optimality of the optimal discrimination design. Figure 2 confirms that the generated design shown in Table 1 line 6 satisfies the equivalence theorem and so the design is optimal for discriminating among the 3 models in the problem.

This example can also be converted to a problem in format (2) by choosing weights for the comparisons between different models. In [Atkinson and Fedorov (1975b)] the concept of different weights for each pair was proposed, but no specific examples were provided. As an illustration, if we assign the weights to be \(w_{12} = 0.2, w_{13} = 0.2, w_{23} = 0.6\), in this example we obtain from our algorithm an equally weighted optimal design at two end points \((1, 1, 1)\) and \((-1, -1, -1)\), and the optimality value is 7.4.
Table 1: Features of the Discrimination Design Problems and Optimal Designs for Examples 1-6 in the order listed below

| Number of factors | Number of parameters | CPU time (sec) | Number of support points | $T$-optimal discrimination design | Optimal criterion value | Relaxation order pairs $(\tau, r)$ |
|-------------------|----------------------|----------------|--------------------------|---------------------------------|------------------------|-------------------------------|
| 1                 | 2                    | 0.89           | 3                        | $\begin{pmatrix} -1 & 0 & 1 \\ 0.25 & 0.25 \end{pmatrix}$ | 0.25                  | (0,1)                         |
| 1                 | 4                    | 1.11           | 6                        | $\begin{pmatrix} -1 & -0.809 & -0.309 \\ 0.999 & 0.198 & 0.199 \end{pmatrix}$ | 0.003906               | (0,1)                         |
| 2                 | 4.6                  | 0.85           | 4                        | $\begin{pmatrix} 0 & 0 & 4 & 4 \\ -1 & 1 & -1 & 1 \end{pmatrix}$ | 4                      | (0,1)                         |
| 3                 | 7                    | 1.02           | 8                        | $\begin{pmatrix} -1 & 1 & -1 & 1 \\ -1 & -1 & 0.5 & 0.5 \\ 0.1253 & 0.1253 & 0.1251 & 0.1251 \\ -1 & 1 & -1 & 1 \\ 1 & 1 & 1 & 1 \\ 0.1249 & 0.1249 & 0.1247 & 0.1247 \end{pmatrix}$ | 1.26562               | (0,1)                         |
| 7                 | 11                   | 734            | 12                       | See $\xi$ below                 | 175.5728               | (1,2)                         |
| 3                 | 4.7                  | 3.98           | 8                        | $\begin{pmatrix} -1 & -1 & 1 & -1 \\ -1 & -1 & -1 & 1 \\ -1 & 1 & -1 & 1 \\ 0.2779 & 0.0555 & 0.0554 & 0.0554 \\ 1 & -1 & 1 & 1 \\ -1 & 1 & 1 & 1 \\ 1 & 1 & -1 & 1 \\ 0.1112 & 0.1112 & 0.1112 & 0.2221 \end{pmatrix}$ | 4                      | (0,2)                         |

The optimal design for Example 5 is

$$\xi^* = \begin{pmatrix} -1.0000 & 0.3541 & 0.3541 & -0.2639 & -0.2639 \\ -1.0000 & -1.0000 & 1.0000 & -1.0000 & 1.0000 \\ -1.0000 & 1.0000 & 1.0000 & 1.0000 & -1.0000 \\ -1.0000 & -1.0000 & -1.0000 & 1.0000 & -1.0000 \\ -1.0000 & 1.0000 & -1.0000 & -1.0000 & 1.0000 \\ -1.0000 & 0.3541 & 0.3541 & 0.3541 & -0.2639 \\ -0.8541 & -1.0000 & 0.0000 & 1.0000 & -1.0000 \end{pmatrix}$$
Fig. 2: Plots of sensitivity functions of designs found by our algorithm for Example 6; the left panel is that from the optimal design for discriminating between model 1 and model 3 and the right panel is for discriminating between model 2 and model 3. Both are plotted against a set of discretized points from the design space and they confirm the optimality of the generated designs for this 3-factor experiment with 3 possible mean functions.

6 Discussion

In this paper, we generalize the widely used T-optimality criterion for discriminating between 2 or more multi-factor polynomial models and find an optimal discrimination design by the semidefinite relaxation method. Our experiments use a state-of-the-art software Gloptipoly3 [Henrion et al. 2009] and our experience is that the software typically runs up to a hundred times faster than existing algorithms when there are two models to discriminate; for example, see the CPU times in Duarte et al. (2015).

Our algorithm is also more general in that (i) it is applicable to discriminating three or more models defined on a multi-dimensional design space with polynomial constraints, (ii) it allows the coefficient in each of the polynomial mean functions has different range spaces, (iii) the null model needs not be completely specified which means that the labeling of the models does not affect the result, (iv) it does not require the design space to be discretized and (v) the user does not have to specify the number of support points of the optimal design in advance. We also provide guidelines for the user to determine whether the relaxation order is sufficiently.

We emphasize that optimal designs sought here are very difficult to study analytically and they have interesting properties. We provide two illustrations with claims on optimality that we have verified using the equivalence theorems. First, suppose we change the uncertainty regions for the model parameters in Example 5 from $[0, 4]$ to $[0, 2]$. The generated $T$-optimal design becomes equally supported at two points at $(1, 1, 1, 1, 1, 1, 1)$ and $(-1, -1, -1, -1, -1, -1, -1)$. Second, if we change $\eta_2$ in Example 5 to

$$\eta_2 = \theta_{20} + \theta_{21} x_1^2 + \theta_{22} x_2^2 + \theta_{23} x_3^2 + \theta_{24} x_4^2 + \theta_{25} x_5^2 + \theta_{26} x_6^2 + \theta_{27} x_7^2, \quad \Theta_2 \in [0, 4]^8,$$
the resulting $T$-optimal design has a weight of 0.5 at the point $(1, 1, 1, 1, 1, 1, 1)$, and the rest of the weights is equally supported at 35 points. The point $(-1, -1, -1, -1, -1, -1, -1)$ which was a support point for the original problem is no longer a support point. Figure 3 shows the locations and the weight distribution of the $T$-optimal discrimination design for this case with the modified $\eta_2$. In either of these cases, we were unable to provide an intuitive explanation for the unexpected change in the structure of the $T$-optimal design. Figure 4 displays the sensitivity function of the design for our second modified example which has 36 support points. The left panel uses a dense grid to show there is no violation in general, and the right panel uses a sparse grid to show more clearly that there are 36 support points in total.

![Fig. 3: The $T$-optimal discrimination design found from our algorithm for the modified Example 5. It has half of its weight at $(1, 1, 1, 1, 1, 1, 1)$ and the rest equally distributed among the 36 indices of the support points shown above in the 7-dimensional design space.](image)

A limitation of our methodology is that it only applies to polynomial regression models with several factors. It does not apply to nonlinear models, or even for linear regression models such as fractional polynomials, where the powers in the monomials are certain fractions, or linear models with basis regression functions involving sine and cosine. These are useful directions for future research because fractional polynomials, as an example, are increasingly recognized as more flexible than polynomial models and are increasingly used in the biomedical sciences to model a continuous biological outcome. Another
Fig. 4: The left panel is the sensitivity plot of the T-optimal design constructed using a dense grid to show there is no violation in general, and the right panel is the same plot using a sparse grid to show the 36 support points in total.

limitation is that our method only returns one optimal design, even when there are several ones, including some designs with smaller number of support points.

7 Appendix

We provide here an illustrative MATLAB code for finding the optimal discrimination design in Example 1.

```matlab
r = 2; % half degree
mpol x;
