Gut Microbiome Changes Associated With HIV Infection and Sexual Orientation

Jie Zhou, Yu Zhang, Ping Cui, Lijia Luo, Hui Chen, Bingyu Liang, Junjun Jiang, Chuanyi Ning, Li Tian, Xiaodan Zhong, Li Ye, Hao Liang and Jiegang Huang

Background: Many studies have explored changes in the gut microbiome associated with HIV infection, but the consistent pattern of changes has not been clarified. Men who have sex with men (MSM) are very likely to be an independent influencing factor of the gut microbiome, but relevant research is still lacking.

Methods: We conducted a meta-analysis by screening 12 published studies of 16S rRNA gene amplicon sequencing of gut microbiomes related to HIV/AIDS (six of these studies contain data that is relevant and available to MSM) from NCBI and EBI databases. The analysis of gut microbiomes related to HIV infection status and MSM status included 1,288 samples (HIV-positive (HIV+)) individuals, n = 744; HIV-negative (HIV-) individuals, n = 544) and 632 samples (MSM, n = 328; non-MSM, n = 304), respectively. The alpha diversity indexes, beta diversity indexes, differentially enriched genera, differentially enriched species, and differentially enriched Kyoto Encyclopedia of Genes and Genomes (KEGG) functional pathways related to gut microbiomes were calculated. Finally, the overall trend of the above indicators was evaluated.

Results: Our results indicate that HIV+ status is associated with decreased alpha diversity of the gut microbiome. MSM status is an important factor that affects the study of HIV-related gut microbiomes; that is, MSM are associated with alpha diversity changes in the gut microbiome regardless of HIV infection, and the changes in the gut microbiome composition of MSM are more significant than those of HIV+ individuals. A consistent change in Bacteroides caccae, Bacteroides ovatus, Bacteroides uniformis, and Prevotella stercorea was found in HIV+ individuals and MSM. The differential expression of the gut microbiome may be accompanied by changes in functional pathways of carbohydrate metabolism, amino acid metabolism, and lipid Metabolism.

Conclusions: This study shows that the changes in the gut microbiome are related to HIV and MSM status. Importantly, MSM status may have a far greater impact on the gut microbiome than HIV status.

Keywords: HIV, AIDS, sexual orientation, gut microbiome, 16S rRNA gene amplicon sequencing
INTRODUCTION

Early studies have shown that the intestinal mucosa is the primary site of early HIV-1 reproduction, irrespective of the way in which HIV-1 invades the body, whether by sexual contact or blood transfusion (Mehandru et al., 2004). HIV-1, which enters the intestinal mucosa at the very early stages of infection, can cause the Th17 CD4+ T cells of the intestine to be destroyed and depleted and the integrity of the intestinal mucosa to be impaired (Epple et al., 2010; Hirao et al., 2014). In addition, gut microbiome translocation can occur, and the gut microbiome and its products can enter the systemic blood circulation (Balagopal et al., 2008), eventually leading to activation of the immune system and spread of the HIV-1 infection (Brenchley et al., 2017).

In recent years, exploration of the role and mechanism of the gut microbiome in the development of HIV infection has gradually become a popular topic of academic research. However, there is still inconsistent evidence about the alpha diversity and composition of the gut microbiome after HIV infection. Most current studies suggest that HIV+ status is related to the downregulation of alpha diversity in the gut microbiome (Mutlu et al., 2014; Yu et al., 2014; Nowak et al., 2015; Dubourg et al., 2016; Noguera-Julian et al., 2016; Pinto-Cardoso et al., 2017; Vesterbacka et al., 2017; Villanueva-Millan et al., 2017). Some researchers (McHardy et al., 2013; Dinh et al., 2015; Nowak et al., 2017) also compared the alpha diversity of the gut microbiome in HIV+ and HIV– individuals, but no significant difference was found. The study by Lozupone et al. (2013) showed that the alpha diversity of the gut microbiome in HIV+ individuals who did not receive antiretroviral therapy (ART) was significantly higher than that of HIV– individuals. Moreover, in many studies, there are inconsistent results regarding the change in the composition of the gut microbiome after HIV infection. Some studies have shown that the abundance of Prevotella increases significantly and the abundance of Bacteroides decreases significantly in HIV+ individuals compared to HIV– individuals (Vujkovic-Cvijin et al., 2013; Dillon et al., 2014; Mutlu et al., 2014; Vázquez-Castellanos et al., 2015; Sun et al., 2016; Yang et al., 2016; Armstrong et al., 2018; Neff et al., 2018). However, a study by Noguera-Julian et al. (2016) showed that the increase in the Prevotella/Bacteroides ratio is associated with MSM status rather than HIV status, which has since been corroborated by several other studies (Armstrong et al., 2018; Neff et al., 2018; Li et al., 2019). Although many studies have explored the changes in the gut microbiome associated with HIV infection, the pattern of these changes has not been elucidated. MSM status is very likely an independent influencing factor of the gut microbiome, but there is still a lack of relevant research to explore it.

In addition, HIV infection can cause dysregulation of multiple functional pathways in the human body (Vázquez-Castellanos et al., 2015, 2018). On the one hand, HIV-related gut microbiomes are well-adapted to inflammatory environments, such as the high expression of the anti-oxidative stress response pathway and the low expression of the anti-inflammatory response process. On the other hand, the gut microbiome can promote the occurrence and development of intestinal inflammation. Therefore, exploration of the functional changes related to HIV infection based on the gene expression profile of the gut microbiome can increase our understanding of the interaction between the gut microbiome and the human body.

To clarify the diversity of the gut microbiome related to HIV infection, to determine whether MSM status is an independent factor influencing the gut microbiome, and to explore the consistent change in the gut microbiome and functional pathways in HIV+ individuals and MSM, we screened 12 published studies of 16S rRNA gene amplicon sequencing of the gut microbiome related to HIV/AIDS (six of these studies contain data that is relevant and available to MSM) from NCBI and EBI databases. The alpha diversity indexes, beta diversity indexes, genera, species, and KEGG functional pathways related to the gut microbiome were calculated. Finally, the overall trend in the above indicators was evaluated.

MATERIALS AND METHODS

Research Strategy

Studies of human fecal flora related to HIV/AIDS by 16S rRNA gene amplicon sequencing before October 2019 were retrieved from the NCBI and EBI databases. Studies were screened according to the following inclusion and exclusion criteria: (1) cross-sectional studies, (2) each sample should give the HIV status of the corresponding subject, (3) the sample types of the sequences should be stool or rectal swabs, and (4) the sequencing method should be 16S rRNA gene amplicon sequencing. Studies with sample sizes of HIV+ or HIV– individuals of <5 were excluded. The technical route of the study is shown in Figure 1.

Processing of Raw Data

The raw sequences were processed using QIIME version 1.9 (Caporaso et al., 2010), and the general process included FLASH software (Magoc and Salzberg, 2011) used for splicing paired-end 16S rRNA gene reads. After splicing, Cutadapt was used for removing primers from the sequences, and low-quality sequences were removed. Based on the chimera database of UCHIME (Edgar et al., 2011), Usearch version 6.1.554 was used to identify and remove chimeras in the sequences, and open reference operational taxonomic unit (OTU) picking was performed with UCLUST (Edgar, 2010) against the Greengenes database (DeSantis et al., 2006), version 13.8, with a similarity of at least 97% (Rideout et al., 2014). The analysis after clustering used the platforms of Microbiome Analyst (Dhariwal et al., 2017), R 3.5.1, Galaxy (Goecs et al., 2013), and REVMAN 5.3.

Data Filtering

Data filtering is done to remove low quality or uninformative features to improve downstream statistical analysis. The minimum count and prevalence in the samples (%) were filtered according to the characteristics of each dataset, which may be caused by sequencing errors or low levels of contamination in the sample. At the same time, for the features that were close to constant throughout the experiment, which are conditions that are not likely to be associated with the conditions under study,
we used the interquartile range (IQR) to detect their variances and filters.

**Data Normalization**
To address the variability in the sampling depth and the sparsity of the data in order to enable more biologically meaningful comparisons, we used total sum scaling (TSS) to bring all samples to the same scale by dividing the samples by a scaling factor.

**Data Analysis**
At the OTU level, to assess alpha diversity, richness (Observed, Chao1, and ACE) and diversity (Shannon, Simpson, Fisher, and Invsimpson) indexes were calculated. Differences between two groups were analyzed via the Student’s t-test and the Mann–Whitney U-test. For principal coordinates analysis (PCoA), distance matrices were calculated using the Bray–Curtis, Jensen–Shannon divergence, and Jaccard ecological dissimilarity indexes. The permutational multivariate analysis of variance (PERMANOVA) test was performed on this distance matrix.

The function of the gut microbiome was inferred using a phylogenetic investigation of communities by reconstruction of unobserved states (PICRUSt) (Langille et al., 2013) in the Greengenes database. In brief, the general process corrected the OTU table for multiple 16S copy numbers. Then, the normalized phylotype abundance was multiplied by the respective set of gene abundances, represented by the KEGG, to identify estimates for each taxon. The accuracy of the KEGG prediction results was evaluated by the nearest sequenced taxon index (NSTI). For the identification of different genera, species, and KEGG functional pathways, we used the linear discriminant analysis effect size.
(LEfSe) method to perform the identification (LDA score was \( \geq 2 \)) and the DESeq2 and Random Forests methods to verify the results of LEfSe.

REVMAN 5.3 software was used to build the forest plots based on the alpha diversity indexes, and Chi² and I² were used for heterogeneity testing for each study. If \( p > 0.1 \) or \( I^2 < 50\% \), the constructed model is not heterogeneous. Sensitivity analysis removes the study with the largest sample size and non-European/non-U.S. studies and converts the fixed effects model (FEM) to the random effects model (REM). All \( p \)-values were corrected for multiple comparisons through the false discovery rate (FDR) technique. All tests were two-sided, and an FDR \( p < 0.05 \) was considered statistically significant.

RESULTS

Study Description

A total of 36 studies related to HIV infection were retrieved from the NCBI and EBI databases. Twelve studies were finally selected for subsequent analysis. The total number of samples included in the overall analysis was 1,288 (HIV+ individuals, \( n = 744 \); HIV– individuals, \( n = 544 \)). Six of the 12 studies contain data that is relevant and available to MSM status, including 632 samples (MSM, \( n = 328 \); non-MSM, \( n = 304 \)). The metadata variables were HIV status, age, gender, body mass index (BMI), MSM status, ART use, CD4+ T cell count, and HIV viral load (VL). A summary of the included studies is presented in Table 1. The unfiltered sequencing quality results are presented in Supplementary Table 1.

Richness and Diversity of the Gut Microbiome Based on HIV Status

The calculation results of the alpha diversity indexes of the OTU level of 12 studies are shown in Table 2. Before controlling for other confounding factors, the alpha diversity of the HIV+ individuals was significantly lower than that of the HIV– individuals, including the ACE (\( Z = 2.92, \text{FDR } p = 0.009 \)), Shannon (\( Z = 3.44, \text{FDR } p = 0.004 \)), Simpson (\( Z = 2.37, \text{FDR } p = 0.028 \)), and Insimpson indexes (\( Z = 2.85, \text{FDR } p = 0.009 \)) of the FEM. The results after the sensitivity analysis remained consistent. The forest maps (Figure 2a, Supplementary Figure 1) and boxplots (Figure 3) of the 12 studies included also showed this trend.

Restricting the Analysis to Gender, Sexual Orientation, Age, and BMI

The subgroup analysis controlled for gender, including 472 men and 175 women. In men, there was no significant difference in alpha diversity between HIV+ and HIV– individuals (Supplementary Figure 2). Among women, HIV+ status was associated with a significant decrease in alpha diversity, including Observed (\( Z = 3.28, \text{FDR } p = 0.035 \)) and ACE (\( Z = 2.52, \text{FDR } p = 0.035 \)) (Figure 2b, Supplementary Figure 3). In MSM (\( n = 316 \)), there was no significant difference in alpha diversity between HIV+ and HIV– individuals (Supplementary Figure 4). In non-MSM (\( n = 288 \)), HIV+ status was associated with a significant decrease in alpha diversity, including Observed (\( Z = 3.32, \text{FDR } p = 0.006 \)), Chao1 (\( Z = 2.69, \text{FDR } p = 0.010 \)), ACE (\( Z = 2.89, \text{FDR } p = 0.010 \)), Shannon (\( Z = 2.89, \text{FDR } p = 0.010 \)), and Simpson (\( Z = 2.81, \text{FDR } p = 0.009 \)) (Figure 2c, Supplementary Figure 5). When age (\( \text{age } \leq 45 \text{ years}, n = 409; \text{age } \geq 45 \text{ years}, n = 288 \)), and BMI (BMI \( = 18.5–23.9, n = 206; \text{BMI } = 24–27.9, n = 201; \text{BMI } > 28, n = 133 \)) (Supplementary Figures 6–10) were controlled, there was no significant difference in alpha diversity between HIV+ and HIV– individuals. The results after the sensitivity analysis remained consistent. Restricting the Analysis to CD4+ T Cell Count, ART, and HIV Viral Load

The subgroup analysis controlled for the CD4+ T cell count, including 146 HIV+ individuals with a CD4+ T cell count of \( < 500, 272 \text{ HIV+ individuals with a CD4+ T cell count of } \geq 500, \) and 217 HIV– individuals. HIV+ individuals with a CD4+ T cell count of \( < 500 \) have significantly lower alpha diversity than HIV– individuals (Shannon (\( Z = 2.78, \text{FDR } p = 0.035 \))). However, there is no significant difference in the alpha diversity of HIV+ individuals with a CD4+ T cell count of \( \geq 500 \) compared to HIV– individuals (Figure 2d, Supplementary Figures 11, 12). When controlled for the ART, including 188 HIV+ non-ART users, 240 HIV+ ART users, and 294 HIV– individuals. The results showed that the alpha diversity of HIV+ non-ART users was significantly lower than that of HIV– individuals (Shannon (\( Z = 2.91, \text{FDR } p = 0.021 \))), and the difference was not found in HIV+ ART users and HIV– individuals (Figure 2e, Supplementary Figures 13, 14). In the stratified analyses examining the HIV VL (VL \( \leq 200, n = 244; \text{VL } > 200, n = 174; \) and HIV– individuals, \( n = 217 \)) was not significantly associated with alpha diversity (Supplementary Figures 15, 16). The results after the sensitivity analysis remained consistent. Restricting the Analysis to CD4+ T Cell Count, ART, and HIV Viral Load

The subgroup analysis controlled for the CD4+ T cell count, including 146 HIV+ individuals with a CD4+ T cell count of \( < 500, 272 \text{ HIV+ individuals with a CD4+ T cell count of } \geq 500, \) and 217 HIV– individuals. HIV+ individuals with a CD4+ T cell count of \( < 500 \) have significantly lower alpha diversity than HIV– individuals (Shannon (\( Z = 2.78, \text{FDR } p = 0.035 \))). However, there is no significant difference in the alpha diversity of HIV+ individuals with a CD4+ T cell count of \( \geq 500 \) compared to HIV– individuals (Figure 2d, Supplementary Figures 11, 12). When controlled for the ART, including 188 HIV+ non-ART users, 240 HIV+ ART users, and 294 HIV– individuals. The results showed that the alpha diversity of HIV+ non-ART users was significantly lower than that of HIV– individuals (Shannon (\( Z = 2.91, \text{FDR } p = 0.021 \))), and the difference was not found in HIV+ ART users and HIV– individuals (Figure 2e, Supplementary Figures 13, 14). In the stratified analyses examining the HIV VL (VL \( \leq 200, n = 244; \text{VL } > 200, n = 174; \) and HIV– individuals, \( n = 217 \)) was not significantly associated with alpha diversity (Supplementary Figures 15, 16). The results after the sensitivity analysis remained consistent.

Composition of the Gut Microbiome Associated With HIV+ and MSM Status

We explored the potential influence of HIV and MSM status on the composition of the gut microbiome, according to the PERMANOVA test of ecological distances. PCoA ordination plots of Bray–Curtis showed that samples from works by Lozupone et al. (2013) ($R^2 = 0.154, FDR p < 0.001$), Dubourg et al. (2016) ($R^2 = 0.080, FDR p < 0.001$), and Armstrong et al. (2018) ($R^2 = 0.059, FDR p < 0.001$) were significantly clustered according to HIV status (Figure 6, Table 4). The samples from works by Noguera-Julian et al. (2016) ($R^2 = 0.122, FDR p < 0.001$), Vesterbacka et al. (2017) ($R^2 = 0.081, FDR p < 0.001$), Armstrong et al. (2018) ($R^2 = 0.090, FDR p < 0.001$), and Li et al. (2019) ($R^2 = 0.115, FDR p < 0.001$) showed better clustering according to MSM status rather than HIV status (Figure 7, Table 5).

We identified the genus and species that cause changes in the composition of the gut microbiome of HIV+ individuals and MSM. In at least three studies, the genus of Bacteroides, Coprococcus, Faecalibacterium, and SMB53 and the species of Bifidobacterium adolescentis, Bacteroides cacaoe, Coprococccus catus, Parabacteroides distasonis, Akkermansia muciniphila, Blautia obeum, Bacteroides ovatus, Faecalibacterium prausnizii, and Bacteroides uniformis were significantly reduced in HIV+ individuals. The species of Prevotella stercora was significantly increased in HIV+ individuals (Figure 8).

In MSM, the genus of Catenibacterium, Eubacterium, Mitsukokella, Phascolarctobacterium, Prevotella, and Slackia and the species of Eubacterium biforme, Prevotella capri, and Prevotella stercora were significantly increased, and the genus of Adlercreutzia, Bacteroides, Bifidobacterium, Bilophila, Holdemania, Odoribacter, Parabacteroides and the species of Bacteroides caccae, Parabacteroides distasonis, Bacteroides ovatus, Ruminococcus torques, and Bacteroides uniformis were significantly reduced (Figure 9).

Differential KEGG Functional Pathway Analysis

We analyzed the differential functional pathways of KEGG related to HIV and MSM status. For HIV status, there were 91 differential KEGG III functional pathways that co-exist in multiple studies (≥3 studies). For MSM status, there were 97 differential KEGG functional pathways that co-exist in multiple studies (≥3 studies). Among HIV+ individuals and MSM, most of the KEGG III pathways under metabolism were downregulated, and most of the KEGG III pathways under genetic information processing were downregulated (Figures 10, 11). For example, in HIV+ individuals and MSM, carbohydrate-metabolism-related pathways of galactose metabolism, pyruvate metabolism, and the pentose phosphate pathway, were downregulated; amino-acid-metabolism-related pathways of histidine metabolism, arginine and proline metabolism, and valine, leucine, and isoleucine biosynthesis, were downregulated; and lipid-metabolism-related pathways of linoleic acid metabolism, primary bile acid biosynthesis, and secondary bile acid biosynthesis, were downregulated. The prediction accuracy of different PICRUSt studies related to HIV and MSM status are shown in Supplementary Table 2 and Table 3.

DISCUSSION

In this study, we collected 12 studies to evaluate the relationship between the gut microbiome and the HIV and MSM status. In the overall assessment of 12 datasets and by restricting the analysis to woman and non-MSM individuals, HIV+ status was associated with decreased alpha diversity, consistent with the results of a recent meta-analysis (Tuddenham et al., 2020). Importantly, when controlling for a CD4+ T cell count of <500 and non-ART, HIV+ status was also significantly associated with decreased alpha diversity. The assessment of the overall effect of six datasets related to MSM status showed that MSM status was associated with decreased alpha diversity, but the results of the subgroup analysis (restricting the analysis to HIV status, age <45 years, age ≥45 years, BMI = 24–27.9) were inconsistent. The analysis of the microbiome composition showed that in multiple studies the samples clustered in different areas of the PCoA coordinate axis according to HIV and MSM status. This clustering phenomenon is more significant between MSM and non-MSM. We also found...
that HIV+ and MSM status were related to consistent changes in the specific genera, species, and KEGG functional pathways.

In recent years, consistent alpha diversity of the gut microbiome associated with HIV infection has not been clarified (Lozupone et al., 2013; Mutlu et al., 2014; Dinh et al., 2015; Dubourg et al., 2016; Nowak et al., 2017). Therefore, we assembled the largest dataset to date to evaluate the alpha diversity of the gut microbiome related to HIV status. Whether in the overall effect analysis based on 12 studies or in the subgroup analysis, our results indicated that HIV+ status was associated with decreased alpha diversity of the gut microbiome, which was consistent with most current research results (Mutlu et al., 2014; Nowak et al., 2015; Dubourg et al., 2016; Noguera-Julian et al., 2016; Vesterbacka et al., 2017; Tuddenham et al., 2020). In our

![dendrogram](image)

**FIGURE 2** | Forest plots comparing HIV+ to HIV− individuals. The fixed effects models (FEMs) with a 95% CI above or below zero were considered statistically significant. The heterogeneity analysis included estimates of \( \chi^2 \) and \( I^2 \). Before controlling for other confounding factors, the alpha diversity of the HIV+ individuals was significantly lower than that of the HIV− individuals (a, Simpson index). When restricting the analysis to women (b, Observed index), non-MSM individuals (c, Simpson index), individuals with CD4+ T cell count of <500 (d, Shannon index), and non-ART individuals (e, Shannon index), HIV+ status was associated with a significant decrease in alpha diversity. The test for overall effect: \( Z = 2.37 (P = 0.02) \).
FIGURE 3 | Boxplots showing the alpha diversity in terms of the Simpson index by study and HIV status (red, HIV– individuals; blue, HIV+ individuals). Most studies showed decreased alpha diversity in HIV+ individuals compared to HIV– individuals.

FIGURE 4 | Forest plots comparing MSM to non-MSM (Non-MSM) individuals. Before controlling for other confounding factors, the alpha diversity of the MSM was significantly lower than that of the non-MSM individuals (a, Simpson index). When restricting the analysis to HIV+ (b, Fisher index), age ≥45 years (c, Fisher index), BMI = 24–27.9 (d, Fisher index) individuals, MSM status was associated with an increase in alpha diversity. When restricting the analysis to HIV– individuals (e, Invsimpson index) and age <45 years (f, Invsimpson index), MSM status was associated with a significant decrease in alpha diversity. MCH also induced changes in the gut microbiome, unrelated to HIV infection. Some authors have implied that MCH may enhance dysbiosis, which is consistent with the high frequency of gastrointestinal symptoms associated with ART (Lozupone et al., 2014; Nowak et al., 2015; Noguera-Julian et al., 2016). In addition, severe mucosal CD4+ T cell depletion is an important reason for disruption of the gut epithelial barrier and translocation of the gut microbiome in the early stage of HIV infection (Hirao et al., 2014). We also confirmed that the CD4+ T cell depletion in HIV+ individuals is closely related to the gut microbiome.
structure of the gut microbiome, which may be stronger than HIV, and this factor may confound many studies of HIV-related gut microbiomes (Noguera-Julian et al., 2016; Kelley et al., 2017; Armstrong et al., 2018; Neff et al., 2018; Guillen et al., 2019; Hensley-McBain et al., 2019; Kehrmann et al., 2019; Li et al., 2019). In our study, a significant reduction in alpha diversity associated with HIV+ status was found in non-MSM individuals, not MSM. Further analysis revealed that there was a significant difference in the gut microbiome alpha diversity between MSM and non-MSM individuals and samples were better clustered in PCoA by MSM, rather than HIV status. These trends reflect previously published results showing that the gut microbiome of MSM has higher immune activity than men who have sex with women (MSW), regardless of HIV infection (Neff et al., 2018; Li et al., 2019).

In addition, many cross-sectional studies have indicated that the gut microbiome shifts from Bacteroides to Prevotella predominance after HIV infection (Lozupone et al., 2013; Mutlu et al., 2014; Vázquez-Castellanos et al., 2015; Ling et al., 2016; Dillon et al., 2017; Serrano-Villar et al., 2017). However, the latest research suggests that the Prevotella predominance is associated with MSM rather than HIV status (Armstrong et al., 2018; Neff et al., 2018; Li et al., 2019). For the inconsistent results of the previous studies, we used LEfSe method to identify the differential genus related to HIV+ and MSM status and used DESeq2 and Random Forests method to verify. Our results
showed that in multiple studies (>3 studies), HIV+ status was related to the abundant downregulation of Bacteroides, Coprococcus, Faecalibacterium, and SMB53, while the Prevotella-rich and Bacteroides-poor were more closely related to MSM status. For the Prevotella-rich not seen in HIV+ individuals, a study found that Prevotella abundance decreased after ART initiation (Nowak et al., 2015). It is worth noting that at the species level, the pattern of microbial composition with decreased abundance of B. caccae, B. ovatus, and B. uniformis and increased abundance of P. stercorea is consistent in HIV+ individuals and MSM. Prevotella spp. is generally considered to have pro-inflammatory effects, whereas Bacteroides spp. has a role in promoting T-regulatory cell function. For example, studies have found evidence that enhanced CD4+T cell HIV infection or inflammation induction is associated with experiments utilizing P. copri or P. stercorea (Dillon et al., 2016; Kaur et al., 2018). Bacteroides is considered to be the main genus of the core microbiome module; of which, the species with relative abundances exceeding 1% are B. uniformis, B. vulgatus, B. cacaee, and B. thetaiotaomicron (Tan et al., 2019). Gauffin Cano et al. demonstrated that the B. uniformis CECT7771 is capable of ameliorating the overweight-associated immune dysfunctions (Gauffin Cano et al., 2012). Hamady et al. (2010, 2011) found that the B. ovatus can prevent colitis caused by DSS in the form of improving weight loss and reducing the colon length, and downregulating the secretion of proinflammatory cytokines such
as TNF-α, IL-1β, and IL-6 (Hamady et al., 2010, 2011). These findings suggest that MSM status may be an independent factor related to dysbiosis of the gut microbiome. Meanwhile, early regulation of MSM-related gut microbiome dysbiosis is of great significance for the prevention and treatment of HIV infection and intestinal inflammation.

The results of the KEGG functional pathway analysis showed gut microbiome—gut microbiome interactions and gut microbiome—human body interactions. For example, a study using gnotobiotic mouse models showed that extracellular digestion of inulin increases the growth rate of B. ovatus. In turn, by-products from inulin catabolism can be used by F. prausnitzii and B. vulgatus (Rakoff-Nahoum et al., 2016). Our research also confirmed this result. That is, in HIV+ individuals, the abundance of carbohydrate metabolism and F. prausnitzii is significantly downregulated with the downregulation of B. ovatus. Comparative analysis of microbial genomes shows that more than 98% of all microbiomes (such as Bacteroides spp.) sequenced so far lack essential pathways or key genes for amino acid synthesis. Therefore, most microbiomes are auxotrophic and require a source of extracellular amino acids, vitamins, and/or cofactors to survive (Mee and Wang, 2012; Mee et al., 2014). Our research also shows that the reduction in the abundance of Bacteroides in HIV+ individuals and MSM was accompanied by the downregulation of amino-acid-metabolism-related pathways.

This study has some limitations. First, we did not collect all demographic and disease characteristics related to the subjects, which leads to a lack of enough datasets for our subgroup analysis. We analyzed the relationship between the gut microbiome and MSM status based on HIV-related data. There are many confounding factors in the analysis related to MSM status, such as age, disease status, and BMI, which are often not matched in HIV-related research, and our included studies are mainly from Europe and the Americas, lacking research from Asia and Africa. Moreover, the shotgun data of the gut microbiome were excluded in our analysis, which might cause flaws in our findings, especially in the bacterial functional pathway analysis. Lastly, the different studies used different variable regions and instruments for 16S rRNA gene amplicon sequencing. Although we have processed and standardized the sequences according to the characteristics of the data, different experimental techniques may still cause bias.

In conclusion, our results clarified that HIV+ status is associated with decreased alpha diversity of the gut microbiome. MSM status was an important factor affecting the study of HIV-related gut microbiomes; that is, MSM was associated with alpha diversity changes in the gut microbiome regardless of HIV infection, and the change in gut microbiome composition of MSM was more significant than that of HIV+ individuals. There was a consistent change in B. cacaee, B. ovatus, B. uniformis, and P. stercorea, in HIV+ individuals and MSM. The differential expression of the gut microbiome was also accompanied by changes in functional pathways, such as carbohydrate metabolism, amino acid metabolism, and lipid metabolism. These findings might help to elucidate the effects of HIV+ and MSM status on the gut microbiome in humans.
