Abstract: Lichen aureus (also called “lichen purpuricus”) is an uncommon subtype of pigmented purpuric dermatosis. Clinically characterized by rust macules, papules or plaques, it is a chronic disease which more often affects young adults and is localized mainly on the lower extremities. The diagnosis is made on the basis of clinical and histopathological features. Dermoscopy findings are useful to confirm clinical diagnosis.

Keywords: Dermoscopy; Diagnosis; Lichenoid eruptions

INTRODUCTION

Lichen aureus (also called “lichen purpuricus”) is an uncommon subtype of pigmented purpuric eruptions.1 Clinically characterized by rust macules, papules or plaques, it is a chronic disease, which more often affects young adults and is localized mainly on the lower extremities.2 The diagnosis is made on the basis of clinical and histopathological features. Dermoscopy findings are useful to confirm clinical diagnosis.3

CASE REPORT

A 54-year-old woman, living in Rio de Janeiro since age 15, reported the appearance of an asymptomatic golden-brown macule on her left ankle, initially (9 months previously) measuring one centimeter and increasing in size over that period (Figure 1).

Figure 1: Unilateral golden-brown macule on left ankle. Presence of purpuric dots within the lesion
Dermoscopy showed coppery-red pigmentation on background, permeated by dark brown network. In addition, linear vessels in the central portion of the lesion accompanied by punctate vessels and of peculiar circular conformation, especially in the periphery of the lesion (Figures 2 and 3).

Skin biopsy and histopathological examination showed vacuolization of the basal layer of the epidermis, lichenoid infiltrate in the dermis, extravasation of red blood cells and hemossiderin within macrophages (Figure 4).

Occlusive therapy with 0.05% clobetasol propionate was performed for three months, resulting in little improvement.

**DISCUSSION**

*Lichen purpuricus* was first described in 1958 by Martin as a case for diagnosis. In 1960 Calnan reported a similar case of lichenoid pigmented lesion (*lichen aureus*). Clinically, this dermatosis presents itself as macules, papules or plaques of varying sizes, rust or cupric coloration (golden), and sometimes may or may not show purpuric dots. The lesions, in most cases, are asymptomatic, unilateral and solitary, but they may manifest in local pain and itching. When multiple, they have linear arrangement with or without segmental and zosteriform distribution. They are located more frequently at lower extremities, and can also affect upper extremities, hands, trunk and eyelids. Differential diagnoses are other pigmented purpuric eruptions, traumatic bruises, purpura caused by drugs, contact dermatitis, mycosis fungoides and atypical forms of histiocytosis.

Histopathology shows little or no epidermal alteration. In the dermis can be noted inflammatory typically band-like infiltrate of lymphocytes and histiocytes, extravasation of erythrocytes and hemosiderin within histiocytes. The infiltrate, which in half of the cases spares the Grenz zone, tends to be denser than in other pigmented purpuric eruptions, and can be confused with that seen in early stages of mycosis fungoides. There are also fewer extravasated red blood cells than in other pigmented purpuric eruptions.

Dermoscopy is a non-invasive method which complements clinical examination and allows the physician directly to evaluate pigmented skin lesions. It has also been used in other areas of dermatology since there is a correlation between the morphological structures of these dermatoses and histopathological findings.

As published by Zaballos *et al*, describing the dermoscopy pattern of three cases of *lichen aureus*, the image may exhibit a diffuse copper background, with red globules, plaques and round-to-oval dots, some gray dots and a network of interconnected pigmented
lines. The dermoscopy representation of dermal lymphohistiocytic infiltrate, together with extravasated red blood cells and hemosiderin-containing macrophages, found at histopathology, is given by the coppery background. The dilated blood capillaries can be seen as red points, plaques and globules, with basal layer hyperpigmentation and incontinentia pigmenti represented by pigmented network lines.

Dermoscopy can be useful to support the clinical diagnosis of lichen aureus. This article contributes to describing the characteristic dermoscopic patterns of this condition, but further studies are required for them to be more precisely defined.
