Abstract. The monitoring of reinforced concrete structures allows us to detect the presence of aggressive agents into of the concrete matrix, on site and in a real time. These aggressive agents can produce the unexpected failure of the structures, thus discovering their presence is a fundamental aspect in the preservation of people safety and the durability of the structure. On the other hand, helps to reduce the cost of maintenance and repair operations, due to allow us to identify the problems faster, minimizing the intervention to be done. The present research paper was focused in the hydronium detection; the reduction of this species generates hydrogen, the hydrogen produces the embrittlement and cracking of the steel, which seriously compromises the right behaviour of the structure. The problem of hydrogen appears in industries such as ammonia processing or petrochemistry industries and nuclear power plants. All of them are industries in which a failure seriously compromises the welfare of people and the environment. Therefore, the detection of hydrogen penetration in reinforcement concrete structures in these cases are very interesting. In this study, with the purpose to detect the hydronium or hydrogen in the hardened concrete matrices is proposed the use of voltammetric sensor, which is part of a multisensory system called Electronic-Tongue. This is a preliminary study. The objective of these initial steps was to evaluate the detection capability of the sensor. Currently, have been designing a sequential test in order to evaluate the sensor in different partial hydrogen pressures with the purpose to develop mathematical models to the hydronium or hydrogen detection and quantification in hardened concrete matrix.

Keywords: Durability, Monitoring, Sensors, Hydrogen Embrittlement.

1 Introduction

The detection of hydronium and hydrogen availability variations in the reinforcement concrete structures is interesting due to the presence of $\text{H}^+/\text{H}_2$ are involve in reactions that produce the durability loss of the structures.

The reaction and molecular recombination of the hydrogen with metals have a greatly impact on their mechanical properties (C A Zapfpe, Member, Sims, and Aime, 1941; Mansilla, Brandaleze, and Ines, 2018; Schroeder and Müller, 2003). In the case of the steels we can classify the damage produced by the hydrogen in:

- High-temperature Hydrogen Attack (Decarburization), in this process the high-temperature (<200°C) reaction of absorbed hydrogen with carbides in the steel results in the decarburization forming methane which can not spread due to the size of its molecules producing intergranular fissuring (Ovejero, 2009).
• Hydrogen-Induced Cracking (HIC), results from the penetration and molecular recombination of atomic hydrogen produced in the steel surface because of a corrosion process. This reaction generates high pressures which produce cracks or blisters in the steel (Ovejero, 2009).

• Hydrogen Embrittlement (HE), produce the decrease of the metal ductility and load bearing capability due to the absorption of hydrogen as atomic or molecular form by the metal. The hydrogen diffuses to the metal grain boundaries producing pressure on the metal grains, this pressures can reach values that reduce the ductility and strength of the steel (Schroeder and Müller, 2003; Industrial Metallurgists, LLC).

In the case of reinforcement concrete structures these problems can produce the brittle failure of the structure (Ramón Zamora, 2018) which seriously threatens the people safety, also the failure generates high economical costs.

These phenomena affect in structures particularly in those industries that work with environments or substances that contain hydrogen. For instance: nuclear reactors, chemical industry, etc. Also, the hydrogen can be generated in structures where is used without any control of the potential the cathodic protection (impressed current) (Byrne, Norton, and Holmes, 2016; Enos, Williams, Clemeña, and Scully, 1998; Ishii, Seki, Fukute, and Ikawa, 1998).

There are other reactions where H$_2$/H$^+$ compromise the reinforcement durability such as the carbonation of the concrete and chlorides attack.

In the carbonation of the concrete the CO$_2$ penetrates reacting with the hydroxide ions and increasing ($H_3O^+$) activity. The pH drop of the concrete pore dissolution will produce the rebars passive layer destruction (Lee, Lee, Min, Lim, and Singh, 2018).

On the other hand, when the chlorides arrive to the rebar surface the following reaction take place (Neville, Wharf, Street, and The, 1995):

\[
\begin{align*}
\text{Fe}^{2+} + 2\text{Cl}^\cdot & \rightarrow \text{FeCl}_2 \\
\text{FeCl}_2 + 2\text{H}_2\text{O} & \rightarrow \text{Fe(OH)}_2 + 2\text{HCl}
\end{align*}
\]

This reaction produces a significant decrease of pH in the local solution inside the pits, so in this area the presence of H$_2$/H$^+$ increase (Andrade, Garcés, and Martínez, 2008).

As is widely known, concrete carbonation and chlorides attack produce the passive layer destruction and the active corrosion of reinforcements starts if thermodynamic conditions are favourable.

Therefore, the increase detection of the H$_2$/H$^+$ can help us to avoid the problems related to the absorption of the hydrogen or hydronium in the steel and also to prevent the corrosion of the rebars when the carbonation of the concrete or the chlorides attack is produced.

With the purpose of preventing or controlling these phenomena will be effective use monitoring systems to control the conditions of the rebars embedded in the concrete and also identify the presence of aggressive substance into of the concrete such as H$_2$/H$^+$.

In this study is proposed the use of a novelty and promising monitoring system formed by cross-sensitivity voltammetric sensor and named Electronic Tongue (e-Tongue). These systems are widely used in the food industry being very effective (Bataller, 2001; Ramón Zamora, 2018).

In this monitoring system, a potential signal vary over time is applied on the sensors, producing the reduction or oxidation over the sensors surfaces of different electroactive species present in the electrolyte, being recorded an electrical current response from each sensor. The
reactions that produce these responses depend on the quantity of the electroactive species and the experimental conditions, such as the sensor material and the potential sweeping range. Therefore, depending on the agents of interest (oxygen, water, chlorides, H⁺/H₂, etc.) the experimental conditions will be defined. Then, by means of multivariate analysis of the sensors response, can be developed forecasting and quantification mathematical models to modelling the presence of the interest substance in the hardened concrete matrix.

In this study was performed an initial evaluation of the Rh voltammetric sensors capability in order to detect variations in the couple hydronium/hydrogen inside of the hardened concrete. These sensors form part of the novel multisensory system e-Tongue, which are currently under development. In a previous work was verified the capability of INOX voltammetric sensors to detect oxygen availability variations inside of the hardened concrete matrix (Martínez-Ibernón et al., 2020) which is going to form part of the e-Tongue.

2 Materials and Methods

Concrete sample (10 cm x10 cm x10 cm) of water/cement ratio 0.4 was made, the composition of the concrete is specified in Table 1.

| Materials         | kg/m³ |
|-------------------|------|
| Cement I 42.5 R-SR5 | 490  |
| Water             | 196  |
| Superplasticizer  | 3.4  |
| Siliceous sand    | 11.5 |
| Aggregate         | 60.1 |

In the concrete sample was embedded one e-Tongue which is under development (Figure 1). This Electronic Tongue are made by a stainless-steel hollow cylinder filling with epoxy resin where are embedded the voltammetric sensors of the e-Tongue.

The purpose of this study is analysed the response of one of the sensors that forms the e-Tongue, this is the Rh voltammetric sensor, this are made with thread of this metal (1mm of diameter and 2mm of length).

The samples were studied in two different conditions:
• State 1: Concrete in atmospheric conditions (dry conditions).
• State 2: Concrete saturated with water. In order to ensuring the higher quantity penetration of water inside of the concrete matrix, the samples were inserted in a deposit with an airtight lid. In this deposit was reached the vacuum conditions by means of a pump, these conditions were kept during three hours. Then was let the entrance of water until the samples were totally submerged. After two hours the vacuum was broken and the specimens were kept submerged in water as show the Figure 2.

Figure 2. Test setup, for submerged conditions (state 2).

Two different testing experiences were defined:

• Experience 1: First, the cyclic voltammetry (CV) technique was applied in the Rh sensor with the sample in state 1 (atmosphere conditions), then, the sample was saturated with water (state 2) and the voltammetry test was repeated in this condition. In the cyclic voltammetry test were applied three potential sweep signals with different potential ranges.

• Experience 2: In this experience, was used a high amplitude cathodic potential pulse (-1.6V amplitude signal), during 3 min, to ensure the generation of atomic and molecular hydrogen. The samples in this experience were in water saturated conditions (state 2). The test sequence was: Previously to apply the potential pulse was tested the sample with a CV, in order to define a baseline of the system conditions, then, the hydrogen generation pulse was applied, finally a cyclic voltammetry was applied. The experience was repeated for two different potential sweeps.

The electrochemical techniques were applied with three electrodes and Autolab PGSTAT10 equipment was used. Specifically, these three electrodes were:

• Reference electrode: a saturated calomel electrode (SCE).
• Counter electrode: Stainless steel lining (Figure 1).
• Working electrode: Rh voltammetric sensor.

The experiences defined allowed us to check the presence of peaks related to reactions associated with the hydronium and the hydrogen. It was possible through the comparation of
the results with the voltagrams for alkaline systems showed in the paper Jaksic, Johansen, and Tunold, (1994).

3 Results and Discussion

The Rh voltammetric sensors used in the Electronic Tongue are capable to detect the presence of hydronium and hydrogen in the concrete matrix. As we can see in the Figure 3, the morphology of the electric current density curve, obtained with the embedded sensor in the conditions of the state 2, is similar to the curve obtained in an alkaline system in dissolution (Jaksic, Johansen, and Tunold, 1994), we can identify the same peaks associated with reactions that involve H⁺/H₂.

However, when the samples are in non-saturated conditions (state 1), meaning the water availability inside of the hardened concrete is very low, the peaks related to the hydronium and hydrogen do not appear (Figure 4).

![Figure 3](https://www.scipedia.com)
On the other hand, after to apply a high amplitude potential pulse with negative value, the generation of hydrogen was assured. The amplitude of the pulse was -1.6 V, at this potential and for pH similar to the concrete (pH≈12.5), water reduction is already taking place, in this reaction H₂ is generated.

The Figure 5 shows how after to apply the cathodic pulse (AP), the peaks associated with the desorption and adsorption of the H⁺/H₂ risen. The increasement of the desorption peaks causes the upward movement of the curve, due to in this potential range the mainly reaction is with H⁺/H₂, whereas previously to the potential pulse application the mainly reaction was the water reduction.

If the test is repeated doing several sweep cycles in each situation (AP and PP), we can see how in the PP situation (previously to the cathodic pulse application) (Figure 6 a) there are a negligible change from initial sweep. However the results obtained when the cathodic potential...
pulse is applied (-1.6V) shows the increase of the total electric density current as cycles are done (Figure 6 b).

This demonstrates that the Rh electrode has a region of potential sensitive to the generation and adsorption/desorption processes of \( \text{H}^+ / \text{H}_2 \). Therefore, this sensor could be used in hardened concrete matrix to detect the species involved in the redox couple.

![Figure 6. Results of Experience 2: a) Voltagram of the system previously cathodic pulse (PP). b) Voltagram of the system after cathodic pulse (AP). C1, C2 and C3 are successive cycles. The zone under examination are pointed with the green rectangle.](image)

3 Conclusions

According to the results, the developing voltammetric sensors are capable to detect variations in the presence of the system hydronium/hydrogen inside of the hardened concrete matrix, and thus the Rh electrode could be useful to determine the pH or the hydrogen activity inside of the materials.
