Abstract

Plant lateral aerial organ (LAO) growth is determined by the number and size of cells comprising the organ. Genetic alteration of one parameter is often accompanied by changes in the other, such that the overall effect on final LAO size is minimized, suggested to be caused by an active organ level ‘compensation mechanism’. For example, the aintegumenta (ant) mutant exhibits reduced cell number but increased cell size in LAOs. The ANT transcription factor regulates the duration of the cell division phase of LAO growth, and its ectopic expression is correlated with increased levels of the cell cycle regulator CYCD3;1. This has previously led to the suggestion that ANT regulates CYCD3;1. It is shown here that while ANT is required for normal cell proliferation in petals, CYCD3;1 is not, suggesting that ANT does not regulate CYCD3;1 during petal growth. Moreover CYCD3;1 expression was similar in wild-type and ant-9 flowers. In contrast to the compensatory changes between cell size and number in ant mutants, cycd3;1 mutants show increased petal cell size unaccompanied by changes in cell number, leading to larger organs. However, loss of CYCD3;1 in the ant-9 mutant background leads to a phenotype consistent with compensation mechanisms. These apparently arbitrary examples of compensation are reconciled through a model of LAO growth in which distinct phases of division and cell expansion occupy differing lengths of a defined overall growth window. This leads to the proposal that many observations of ‘compensation mechanisms’ might alternatively be more simply explained as emergent properties of LAO development.

Key words: AINTEGUMENTA, compensation mechanism, cyclin D, endoreduplication, organ size, petal growth.

Introduction

The final size of higher plant lateral aerial organs (LAOs) varies greatly between species, is affected by environmental conditions, and is of great significance to food and feed production (Johnson and Lenhard, 2011). The size of a plant organ is determined both by the number of cells constituting the organ and by the sizes of the constituent cells (Horiguchi et al., 2006). Compensatory changes in these two parameters are often observed (Truernit and Haseloff, 2008; Larson-Rabin et al., 2009; Kawade et al., 2010; Ferjani et al., 2013; Hisanaga et al., 2013), such that genetic alterations changing cell division often lead to changes in cell size that tend to restore a more normal organ size, and vice versa. These observations have led to the hypothesis of ‘compensation’, a formal mechanism by which an organ-level size control manipulates these two parameters to attempt to maintain a constant size (Tsukaya, 2008). While many genetic
influences on both cell number and size have been described, no clear molecular explanation of the phenomenon of compensation has emerged.

\textit{AINTEGUMENTA} (\textit{ANT}) is a member of the \textit{APETALA2} (\textit{AP2})-like transcription factor (\textit{TF}) family (Kim et al., 2006). \textit{ANT} is the archetypal member of a subfamily of eight \textit{AP2}-like \textit{TFs} with high amino acid sequence similarity designated \textit{AINTEGUMENTA-LIKE/PLETHORA (AIL/PLT) genes}. These are expressed in young dividing tissues and appear to promote states of mitotic competence (Nole-Wilson et al., 2005). \textit{ANT} is required for proper integument development and hence megasporogenesis (Elliott et al., 1996; Klucher et al., 1996), and is involved in the regulation of LAO growth (Krizek, 1999; Krizek et al., 2000; Mizukami and Fischer, 2000); plants lacking functional \textit{ANT} develop smaller leaves and petals (Krizek, 1999; Krizek et al., 2000; Mizukami and Fischer, 2000). In situ hybridization showed the presence of \textit{ANT} mRNA in various tissues within young flowers, reducing as the flowers aged (Krizek, 1999). Overexpression of \textit{ANT}, using the constitutively active 35S promoter, results in larger petals, sepals, stamens, and carpels, and hence larger flowers than normal (Krizek, 1999). Larger cells were observed in the overexpressers than in wild-type (WT) plants, and, since no change in either floral meristem size or cell cycle activity was detected, it was suggested that \textit{ANT} regulates cell size to affect organ size.

Mizukami and Fisher (2000) analysed the consequences of reducing and increasing functional \textit{ANT} expression in the \textit{Arabidopsis thaliana} Col-0 ecotype. The Col-0 \textit{ant-1} mutant also has smaller petals and leaves than WT counterparts (Mizukami and Fischer, 2000). Overexpressors have greater flower mass and rosette growth, and additionally overexpression of \textit{Arabidopsis ANT} in tobacco increases seed size. In contrast to Krizek (1999), who was working in the Ler background, Mizukami and Fisher (2000) found that petals of 35S:\textit{ANT} Col-0 plants contain cells of unchanged size, but an increased number. However, in \textit{ant-1} mutant petals, cell size was increased and cell density and number were decreased, indicating that reduced petal size in this mutant was due to a reduction in cell number. Analyses of \textit{ant} petal phenotypes at different developmental stages led to the conclusion that \textit{ANT} regulates LAO size by regulating the so-called mitotic window, a period of time during LAO growth in which cell proliferation can occur, and not the rate of cell proliferation (Mizukami and Fischer, 2000). The increase in cell size could be seen as evidence for the proposed compensation mechanism buffering changes to LAO size (Tsukaya, 2008).

\textit{CYCD3;1} is the rate-limiting regulatory partner of cyclin D/cyclin-dependent kinase A (\textit{CDKA}) complexes (Dewitte et al., 2003; Menges et al., 2006). These complexes promote the activity of E2F complexes, which induce expression of \textit{S}-phase genes by phosphorylating the RBR protein that otherwise inhibits E2F activity (Oakenfull et al., 2002). Expression of \textit{CYCD3;1} was prolonged in LAOs of 35S:\textit{ANT} plants (Mizukami and Fischer, 2000). Thus \textit{ANT} did appear to sustain cell cycle activity but was not detectably increasing its rate (Mizukami and Fischer, 2000). Expression of \textit{CYCD3;1} was, however, not determined in \textit{ant} loss-of-function mutants. These observations have led to the suggestion that \textit{CYCD3;1} is a target of \textit{ANT} (Schruﬀ et al., 2006; Anastasiou and Lenhard, 2007; Breuninger and Lenhard, 2010). While support for this hypothesis has been obtained for orthologues of \textit{ANT} and \textit{CYCD3;1} in poplar (Karlb erg et al., 2011), whether or not \textit{ANT} regulates \textit{CYCD3;1} in \textit{Arabidopsis} remains unconfirmed.

Here, the hypothesis that \textit{ANT} regulates \textit{CYCD3;1} during LAO growth in \textit{Arabidopsis} is tested. Petals are used as a model for LAO size control, since they are composed of a small number of cell types with a significant number of advantages as a model for morphogenesis (Irish, 2008), including the lack of stomata in the epidermis, allowing the extrapolation of cellular data for an entire organ. Petal growth, like that of leaves, involves an initial phase of cell proliferation, followed by a cell expansion phase (Hill and Lord, 1989), thus facilitating the investigation of the interaction between cell number and size control during LAO growth. Petal cells also display little endoreduplication, a process of genome doubling without cell division that frequently accompanies cell enlargement in other tissues (Hase et al., 2005).

The genetic interaction between \textit{ANT} and \textit{CYCD3;1} was investigated, and the mechanisms by which these genes regulate petal size explored. An additive petal cell size phenotype was observed in an \textit{ant cycd3;1} double mutant. In these double mutants, organ-level control of size appeared to be lost, and petal size was directly correlated with cell size. Moreover, different effects on petal cell ploidy were observed in the respective single mutants. A reduction in \textit{CYCD3;1} transcript abundance could not be detected by quantitative PCR (qPCR) in \textit{ant} mutant shoots, nor could evidence be found for \textit{ANT} binding the \textit{CYCD3;1} promoter in yeast one-hybrid assays, consistent with the alternative proposition that \textit{ANT} does not regulate \textit{CYCD3;1} expression in \textit{Arabidopsis} shoots.

Materials and methods

\textbf{Plant lines and growth conditions}

All experiments with \textit{A. thaliana} plants were performed in the Col-0 (Columbia-0) or Ler (Landsberg erecta) ecotype backgrounds. The cycd3 loss-of-function mutant contains an insertion of a maize DS transposable element in the first exon of \textit{CYCD3;1} (Dewitte et al., 2007). Here the original Ler allele was used. The \textit{ant-9} mutant is also in the Ler background and has been previously described; this mutant contains an insertion of the maize AC transposon within the second intron of \textit{ANT} (Elliott et al., 1996). For soil growth, plants were grown in a controlled environment with 16 h light at 21 °C. A 3:1 potting compost/sand mixture was used. For \textit{in vitro} growth, ‘GM roots’ medium was used for growing plants vertically with the roots on the surface of the medium containing 1.5% agar, 2.3 g l^{-1} Murashige and Skoog (MS) medium, and 0.75% sucrose. Seeds were surface-sterilized with 2.5 mg ml^{-1} sodium dichloroisocyanurate dehydrate (Chlorifix, Bayrol, Germany) in 70% ethanol. Prior to growth, seeds underwent stratification at 4 °C for 3 d. Seedlings were grown in a Percival growth cabinet (Percival Scientific Inc.) with 16 h days at 25 °C.
Genotyping
For DNA isolation, 400 μl of a DNA extraction buffer containing 200 mM TRIS, 250 mM NaCl, 25 mM EDTA, and 0.5% (w/v) SDS was added to homogenized tissue. Samples were briefly vortexed then centrifuged at 13 000 rpm for 1 min. A 300 μl aliquot of supernatant was transferred to a new tube. To this was added an equal volume of ice-cold isopropanol for DNA precipitation. The precipitate was washed in 70% (v/v) ethanol. PCRs were performed in a Mastercycler Pro Thermocycler (Eppendorf AG, Hamburg). GoTaq® (Promega, USA) PCR mix was used. Primers are described in the Supplementary Materials and methods available at JXB online.

Flow cytometry
The CyStain UV Precise P kit (Partec, Japan) was used for extraction of nuclei and DNA staining. The Partec CyFlow Space instrument (Partec, Japan) was used for analysis, using the FL2 channel for laser excitation at 375 nm. Liquid was passed through the machine at 1 μl s−1 and the gain was set to 384. Histograms were created in Cylogic software (CyFlo Ltd, Finland). Pixels belonging to individual peaks were counted using imageJ (NIH, USA).

qPCR
RNA was extracted using the TriPure isolation reagent (Roche, Switzerland). The Ambion® DNA-free kit (Life Technologies, USA) was used to remove the remaining DNA. cDNA was synthesized using the RevertAid® (ThermoScientific, USA) cDNA synthesis kit. qPCR was performed in a Rotorgene 6000 light-cycler (Qiagen, USA) using the pPCRBIOS SyGreen master mix (PCR Biosystems Ltd, UK). mRNA levels were quantified using the 2–ΔΔCT method with ACT2 as a reference gene (Livak and Schmittgen, 2001). Primers are described in the Supplementary Materials and methods at JXB online.

Cellular analysis of petals
Petals were fixed and cleared in a solution of 10% acetic acid, 50% methanol overnight, and incubated for at least an hour in 80% chloral hydrate. Light microscopy was performed with a Zeiss AX10 ImagerM1 (Zeiss, Germany) with an AxioCam MRc5 camera.

Statistics
Student’s t-tests were performed in Microsoft Excel 2011 (Microsoft, USA), were two-tailed, and assumed unequal variance. One-way analysis of variance (ANOVA) was performed in GraphPad Prism 6 (GraphPad Software Inc., USA). The Holm–Sidak test was used for multiple comparisons. Multiplicity adjusted P-values (Wright, 1992) are given. Values are presented as mean ± standard errors (SEs). Pearson’s correlation tests were performed in R (www.r-project.org); r² values are given.

Yeast one-hybrid assay
Strains containing the LacZ reporter downstream of the optimal ANT-binding sequence (ABS) (Nole-Wilson and Krizek, 2000), a sequence from pCYD3:1, or no sequence were created initially. The optimal ABS is flanked by CTGTA at the 5′ end and ACCAAGT at the 3′ end. The putative ANT-binding sequence from pCYD3:1 is flanked by the same sequences at the same relative positions. Yeast of the YM4271 strain (MATa, ura3-52, his3-200, ade2-101, ade5, lys2-801, leu2-3, 112, trp1-901, tyr1-501, gal4Δ, gal8Δ, ade5::hisG) were transformed with NcoI-linearized pLaCZi vectors. Homologous recombination at the UR43 locus results in the integration of a functional UR43 gene, thus restoring uracil prototrophy. Thus transformants were selected for on medium lacking uracil. YM4271 transformants containing the reporters were then transformed with pGAD424 vectors containing ANT or a dominant negative form of ANT (ANTANT) which exhibits DNA-binding activity but no transactivation activity (Krizek and Sulli, 2006).

Yeast colonies from the transformation were streaked onto fresh selective plates. After 2 d of growth, these plates were replica plated onto SD agar plates (2.10.1) containing 80 mg l−1 X-gal and 1× NaPi buffer, pH 7.0. These plates were then incubated at 30 °C for 4–6 d and checked regularly for the development of a blue colour.

Results
Relationship between cell size and petal growth in ant-9, cycd3;1 and ant-9 cycd3;1 mutants
To explore the possibility that ANT regulates CYCD3;1 expression as a means of regulating cell proliferation during LAO development, the genetic interaction between the two loci in petals was investigated. F1 seeds co-segregating for ant-9 and cycd3;1 alleles, both in the Ler background, together with WT Ler and the single mutants, were used to grow plants for analysis of petal size and cellular composition (Fig. 1).

ant-9 mutant petals displayed a 33% reduction in surface area compared with the WT (one-way ANOVA, P<0.0001, df=89) (Fig. 1A, C, F), and a 34% increase in petal adaxial epidermal cell surface area (one-way ANOVA, P<0.0001, df=804) (Fig. 1D, G). Petal epidermal cell numbers making up the adaxial surface were estimated by calculation. ant-9 petals contained an estimated 5407 ± 273 epidermal cells, whereas WT petals contained 10654 ± 47 epidermal cells. ant-9 petals therefore contained about half the number (49%) of the cells contained in WT petals, showing that ant-9 petals are smaller than their WT counterparts due to a reduced number of cells (one-way ANOVA, P<0.0001, df=68) (Fig. 1E), albeit that these cells are larger.

Surprisingly, the mean adaxial surface area of cycd3;1 petals was found to be 38% larger than that of WT petals (one-way ANOVA, P<0.0001, df=89) (Fig. 1A, C, G). The petal adaxial epidermal cell surface area in cycd3;1 mutants was 31% greater than that of the WT (one-way ANOVA, P<0.0001, df=804) (Fig. 1B, D, G). The percentage increase in cell size is similar to the percentage increase in petal adaxial surface area, suggesting that the former accounts for the latter. Accordingly, calculated cell number in the adaxial epidermis was similar in the WT (10654 ± 471) and cycd3;1 (11197 ± 306) petals (one-way ANOVA q=1.656, P=0.65, df=68) (Fig. 1E).

Hence, the ant-9 and cycd3;1 mutants share the phenotype of enlarged cell size, but differ in their effect on cell number, consequently leading to opposite organ size phenotypes.

To investigate the interaction between these two loci in petal development, analyses of double mutants were performed. The mean adaxial surface area of ant-9 cycd3;1 double mutant petals was 21% smaller than that of the WT (one-way ANOVA, P<0.0001, df=89), but 17% larger than that of ant-9 petals (one-way ANOVA, P=0.03, df=89) (Fig. 1A, C, G). This suggests that the combined phenotype is an additive result of the opposite effects of the two individual mutants on organ size, leading to an apparent partial compensation
of the petal size phenotype in ant-9 mutants by the loss of functional CYCD3;1.

Cell size in ant-9 cycd3;1 double mutants was even larger than that observed in either single mutant, and 98% larger than that in WT cells (one-way ANOVA, \( P<0.0001 \), df=804 in each case) (Fig. 1B, D, G). Thus the increased cell size phenotype coming from both alleles also appeared to be additive, suggesting independent action of each gene in contributing to petal adaxial epidermal cell size. The estimated cell number in ant-9 single and ant-9 cycd3;1 double mutants was similar (one-way ANOVA, \( P=0.1 \), df=68) (Fig. 1E), suggesting that ant-9 limits the cell number independently of CYCD3;1.

Petal size is correlated with cell size within the ant-9 cycd3;1 mutant population

It was noted that the range of petal sizes in ant-9 cycd3;1 mutants appeared to be greater than that in any other genotype (Fig. 1C), as did the range of cell sizes (Fig. 1D). This suggested that some petals in the double mutants were
ANT and CYCD3;1 influence petal cell size independently

becoming much larger due to increases in mean cell size within those petals. Plotting cell size against petal size indicated that this indeed seemed to be the case, as the two variables correlated positively in this genotype (Fig. 2) ($r=0.63$, $r^2=0.40$, $P=0.0027$). No such correlation was observed in other genotypes (Fig. 2) ($r^2<0.05$ and $P>0.4$ in each case). Thus ANT and CYCD3;1 both contribute to organ size control, and loss of both leads to change in petal size depending on the sizes of its constituent cells.

Ploidy levels in petal cells of ant and cycd3;1 mutants

An increase in mean cell size was observed in both ant and cycd3;1 loss-of-function mutant petals. Endoreduplication leading to increased ploidy is not normally prevalent in petals, but since in other tissues it is often associated with cell expansion, possible ploidy changes were investigated in ant-9, cycd3;1 and ant-9 cycd3;1 mutants using flow cytometry (Fig. 3). WT petals contained mostly 2C cells, as seen previously in petal tips (Hase et al., 2005). However, a small proportion of cells had a genome content of 4C, and fewer cells were detected that were 8C and 16C (Fig. 3A, E). This may indicate limited endoreduplication in petal cells, although a small amount of contamination from other floral organs cannot be excluded. Although the majority of cycd3;1 petal cells also had a 2C DNA content, relatively more displayed 4C and 8C DNA contents (Fig. 3B, E), an observation similar to that made by Dewitte et al. (2007) in the cycd3;1–3 triple mutant in the Col-0 background. The 4C cells might represent cells in the G2 phase of the cell cycle, but equally those cells might be in the G1 phase of the first round of endoreduplication. However, the relatively greater abundance of 8C cells suggests that a greater proportion of cycd3;1 petal cells undergo endoreduplication than do WT cells, which might contribute to the increase in cell size observed in this mutant.

In contrast, the ant-9 petal cells had ploidy levels in similar proportions to those of WT plants, except that 16C cells were not detected (Fig. 3C, E). The ant-9 cycd3;1 mutant showed a distribution of genome content intermediate between that of the cycd3;1 and ant-9 mutants (Fig. 3D, E). Taken together, these data suggest that endocycling is increased in cycd3;1 mutants, and that more advanced stages of endocycling may require ANT.

The additive petal cell size phenotypes of ant-9 and cycd3;1 mutations suggest that the increase is occurring via independent mechanisms. The observation of a ploidy level increase in cycd3;1 mutants for which ANT is limiting, but no such increase in ant-9 mutants, is consistent with this conclusion.

CYCD3;1 expression is unchanged in ant mutants

The observation of increased CYCD3;1 expression in 35S:ANT plants (Mizukami and Fischer, 2000) has led to the assumption that ANT may regulate CYCD3;1. CYCD3;1 expression was therefore tested in young ant-9 mutant flow- ers containing developing petals. To confirm that the primers used for qPCR analyses were specific for CYCD3;1 transcripts, they were used to measure CYCD3;1 mRNA levels in WT, cycd3;1, and p35S:CYCD3;1 (Dewitte et al., 2003) plants. Transcript levels appeared to be absent in the loss-of-function mutant, and increased >50-fold in the overexpresser (Fig. 4A), indicating that the primers detect specifically CYCD3;1 transcripts. qPCR analyses of RNA extracted from stage 1–12 (Smyth et al., 1990) ant-9 floral

![Fig. 2. Petal size is correlated with cell size in ant-9 cycd3;1 double mutants. Each point represents the average adaxial epidermal cell size (y-axis) of a particular petal, the size of which it is plotted on the x-axis. Thirteen pairs of data are shown for the WT (top left), 19 for ant-9, 20 for cycd3;1, and 20 for the ant-9 cycd3;1 Ler double mutant.](image-url)
buds showed no significant (Student’s t-test, \(P=0.3362, \text{df}=6\)) down-regulation of \(CYCD3;1\) transcript levels compared with WT buds (Fig. 4B). This suggests that ANT is not rate limiting for expression of endogenous \(CYCD3;1\). \(CYCD3;1\) transcript levels were also compared in WT and \(ant-9\) whole shoots, and no down-regulation of \(CYCD3;1\) expression was detected in the \(ant-9\) mutant (Supplementary Fig. S1 at JXB online). Therefore, no large or consistent change in \(CYCD3;1\) transcript abundance was observed, suggesting that, at least in flowers and reproductive shoots, ANT does not regulate \(CYCD3;1\) expression.

A sequence was identified within 200 bp upstream of the \(CYCD3;1\) start codon that closely resembles the optimal ANT-binding sequence, albeit being one base shorter (Fig. 4C). To test further whether ANT regulates \(CYCD3;1\), a yeast one-hybrid assay for binding of ANT to this sequence was performed. While binding of WT ANT to its optimal binding sequence was detected, binding of a dominant-negative form of ANT that contains the DNA-binding domain but lacks the transactivation domain (Krizek and Sulli, 2006) was not, confirming that expression of the reporter in this assay depended on ANT (Fig. 4D). Consistent with ANT not regulating \(CYCD3;1\), binding of ANT to the sequence identified upstream of \(CYCD3;1\) was not detected (Fig. 4D).

**Discussion**

It might be expected that there are several mechanisms to maintain the correct LAO size. The balance between cell division and expansion appears to be organ specific in floral organs (Delgado-Benarroch et al., 2009), supporting the existence of different mechanisms of growth control. Since overall size is dependent on both cell number and cell size, mechanisms that compensate for altered cell proliferation or expansion might be anticipated. Indeed, several categories of apparent organ size compensation mechanisms have been reported, some involving endoreduplication and others not (Cookson et al., 2006; Ferjani et al., 2007; Fujikura et al., 2007; Truernit and Haseloff, 2008; Larson-Rabin et al., 2009), although the molecular basis by which such an organ-level compensation mechanism(s) might operate is unclear. Such mechanism(s) must also be responsive to multiple environmental inputs that alter organ size (Cookson et al., 2006).

In their investigation of the mechanisms by which ANT regulates final LAO size, Mizukami and Fisher (2000) showed that ANT regulates the length of the mitotic window during which cell proliferation can occur during LAO growth, and therefore controls cell number, a conclusion confirmed here. They also showed that constitutive overexpression of \(ANT\) caused ectopic expression of \(CYCD3;1\) in mature leaves. However, it remained unknown whether this was a result of direct regulation of \(CYCD3;1\) expression by ANT.

The molecular analysis conducted here does not support the hypothesis that ANT regulates the expression of \(CYCD3;1\), as qPCR analysis showed similar levels of \(CYCD3;1\) transcripts in \(ant-9\) mutants and WT plants. Genetic analysis of the double mutant showed additive cell size phenotypes. Taken together, these results do not suggest that ANT significantly regulates the expression of \(CYCD3;1\). It nonetheless remains possible that under genotypic, developmental,
and/or environmental contexts other than those involved in this investigation, ANT regulates CYCD3;1, whether directly or not.

As part of the analysis, the phenotypes of the ant and cycd3;1 loss-of-function mutants were reassessed. As reported previously (Mizukami and Fischer, 2000), ant mutant petals are smaller than WT petals, and this is due to a reduction in cell number. Cell size was increased, but not sufficiently to account for the loss of cell number, leading to smaller petals. The cell size increase may simply indicate that ANT normally acts to suppress cell growth, or can be interpreted as the action of an overarching compensation mechanism attempting to regulate LAO size. In contrast, cycd3;1 mutant petals were found to be comprised of a similar number of cells to WT Ler petals. Therefore, CYCD3;1 does not appear to regulate petal number in this background. As observed by Dewitte et al. (2007), cell size was increased in cycd3;1 mutants. Thus CYCD3;1 might play a role linking cell division and cell expansion in petals.

To investigate the functional interaction between ANT and CYCD3;1, the petals of double ant-9 cycd3;1 loss-of-function mutants were analysed. This revealed a genetic interaction between ant and cycd3;1 in terms of petal size, as the increased size of cycd3;1 petals apparently partially suppressed the smaller petal phenotype of the ant-9 mutant. This appeared to be due to an additive cell size increase from both mutant alleles, compensating for the loss of cell number caused by the ant allele. This suggests that at least some of the roles of ANT and CYCD3;1 in the regulation of petal growth are exclusive to one factor or the other.

The mechanism by which cell expansion is utilized to compensate for reduced final organ size in ant mutants is not understood. Cell size in the epidermis is often associated with increased ploidy levels due to endoreduplication (Kondorosi et al., 2000). ant-9 mutant petals showed a ploidy distribution similar to that in the WT. cycd3;1 single and ant-9 cycd3;1 double mutants showed a relative increase in the abundance of cells with a 4C DNA content, representing either mitotic cells in the G2 phase of the cell cycle or cells in the G1 phase of the first round of endoreduplication (Larkins et al., 2001). cycd3;1 mutants, but not ant-9 cycd3;1 mutants, showed an increase in the abundance of cells with an 8C genome content. cycd3;1–3 mutant petals also have cells with greater ploidy levels (Dewitte et al., 2007). This shows that CYCD3;1 inhibits the onset of endocycling, and suggests that increased endocycling may contribute to cell size increase in cycd3;1 mutants. Increased cell expansion occurs independently of endoreduplication in ant mutants. Reduction in LAO size by shading and water deficit also increases cell size and reduces cell number without any change in ploidy distribution (Cookson et al., 2006); hence, control of cell expansion as part of a compensation mechanism does not necessarily involve its coupling with cell cycle activity or endoreduplication. Loss of functional ANT might lead to early differentiation and cell expansion of LAO cells. Supporting such a role for ANT in limiting the onset of cell differentiation, overexpression of ANT using the 35S promoter appears to suppress senescence in flowers (Krizek, 1999). Since the mechanisms of cell size increase in ant-9 and cycd3;1 mutants appear to be different, it is perhaps not surprising that the cell size phenotype in the double mutant is additive.

ANT is highly conserved in higher plants (Kim et al., 2006), and has been shown to promote organ growth in species other than Arabidopsis, for example apple (Dash and Malladi, 2012). In hybrid aspen trees, AIL genes regulate the growth cessation response of meristems to short days (Karlb erg et al., 2011). AIL1 is expressed in the shoot apical meristem and leaf primordia, and short-day exposure down-regulates AIL1 expression and expression of the aspen CYCD3 homologue. In the case of hybrid aspen, AIL1 can interact with the
promoter of the cyclin D3 gene CYCD3:2, and down-regulation of D-type cyclin expression by short days is prevented by AIL1 overexpression. This suggests that in some species there is a closer relationship between AIL gene function and CYCD3 activity, indicative of their involvement in common pathways of growth regulation. However, in the present analysis using Arabidopsis Ler, no genetic or molecular evidence directly linking ANT itself and CYCD3:1 was found, although this does not exclude the possible involvement of other AIL/PLT genes. The robust identification of AIL/PLT targets in Arabidopsis would throw more light on the mode of action.

Is organ size an emergent and not a determined property?

The proposition of a compensation mechanism for controlling organ size, playing cell number and cell size against each other, implies that an organ-level control exists that can measure organ size. Since cell division stops well before plant organs reach their final size, this would imply the capability to predict subsequent organ size.

Compensation mechanisms have been widely proposed and analysed (Ferjani et al., 2007; Kawade et al., 2010; Horiguchi and Tsukaya, 2011), but remain rather enigmatic. A detailed clonal analysis by Kawade et al. (2010) showed that both cell-autonomous and non-cell-autonomous mechanisms can coordinate cell proliferation and post-mitotic cell expansion in leaves, and that an unknown signal can move across boundaries between sectors of tissue and induce compensation.

The analysis of organ size in the double ant-9 cycd3;1 mutant reveals a novel phenotype. This displays a highly variable petal size, correlated with cell size, indicative of the loss of much organ-level control. It is also noted that the increased size of cycd3;1 mutant petals is not consistent with the compensation hypothesis, since some reduction in cell number might be anticipated to compensate the modest increase in cell size.

The plant organ is composed of individual cells that grow and divide (Fig. 5), and as such represents a complex system—formally defined as ‘a set (whole) of entities (cells) that interact according to simple local rules’. Because of interactions and feedbacks between cells, both chemical and physical due to cell wall interconnections, the emergence of system properties cannot be deduced from the simple local properties of the cells.

It is proposed that organ size arises as an emergent property of the complex system represented by cells of which it is composed, and the controls and feedback that affect the division and growth of individual cells. In this view, compensation may be the observed phenotypic output of multiple parallel mechanisms whose apparent effect is ‘compensation’, but whose operation is not determined by a ‘master supra-cellular control’ of organ size. Hence, in this case, ‘compensation’ would be not a mechanism but rather a phenotypic observation of consequences of the interplay of other processes. This would explain why sometimes compensation appears to occur, whereas in other situations it does not. It may also explain how compensation can appear to operate in different modes (Kawade et al., 2010).

Breuninger and Lenhard (2010) have previously suggested that the final size of LAOs might be pre-determined by a cell number-independent parameter, and that cell division and expansion occur until the value of this parameter is reached. It is suggested here that the present data could rather be explained by the existence of a ‘growth window’ in

---

**Fig. 5.** Model of petal growth involving distinct division and expansion phases normally constrained within a fixed overall growth window. The phases can alter in relative length as a consequence of genetic changes, as can division and expansion rates within these phases. (A) Normal growth window comprised of a blue section when division accompanies growth, and a red section when only growth occurs. Growth proceeds at a constant rate throughout the window. (B) Division extended throughout the period of the growth window. The increased number of cells appears to be ‘compensated’ by a reduced cell size. (C) Division stops earlier than normal in the growth window. The reduced number of cells appears to be ‘compensated’ by increased cell size. (D) In the ant-9 mutant, division stops earlier, but the overall growth window is also curtailed, resulting in fewer but larger cells, in an apparent attempt to ‘compensate’ for reduced cell number. The curtailed growth window leads to a smaller organ and partial ‘failure’ of compensation. (E) In the cycd3:1 mutant, division continues as normal, but the rate of growth is increased during the second phase.
organ development producing a certain amount of tissue area before growth stops (Fig. 5). During this growth window, cell division is independently controlled, so that the area of tissue can be composed of more or fewer cells (Fig. 5). Such a growth window would lead to apparent compensation, with fewer divisions producing larger cells, and more divisions producing smaller cells (Fig 5).

ANT acts to control the length of the first part of the overall growth window in which division is active, hence fewer cells in the mutant and more cells in ANT overexpressers. The earlier cessation of division in ant-9 mutants allows more time for growth, hence larger cells. ANT also controls the length of the overall window, leading to reduced organ size (Fig. 5D). ANT overexpression lengthens the window since it results in more cells of normal size, and larger organs.

CYCD3;1 constrains growth by limiting endoreduplication, and hence controls the second (non-division) phase of the overall growth window. Hence, loss of CYCD3;1 leads to increased cell size (Fig. 5E). Loss of both genes leads to loss of control of the earlier (division) phase of the growth window (as in ant-9), together with loss of cell size control in the second phase. This loss of control of both phases of the overall growth window leads organ size to become more variable, as was observed here, and directly related to average cell size.

Consistent with these observations, it is therefore proposed that many apparent compensation mechanisms of cell size and number may reflect the emergent property of these individual molecular controls rather than a pre-determined organ-level control. It is believed that this view can provide a more coherent systems-level framework for future understanding of mutants that change cellular parameters.
