**Background:** The prognosis of cancer survivors has dramatically improved, but effective strategies for cancer treatment-related cardiovascular disorders (CTRCD) remain to be elucidated in the emerging field of cardio-oncology. In this study, we investigated risk factors for CTRCD in breast cancer patients treated with trastuzumab.

**Methods and Results:** We performed a retrospective analysis of 141 consecutive women who received adjuvant trastuzumab, and underwent baseline (BL) and follow-up (FU) echocardiography at Juntendo University between April 2010 and December 2016. The major concomitant treatment was anthracyclines in 94% and radiotherapy in 53%. During the median treatment period of 11 months, there were 22 (15.6%) cardiology consultations, 3 (2.1%) treatment interruptions with irreversible CTRCD, and no deaths. Left ventricular ejection fraction (LVEF) was decreased from a median 67.5% (BL) to 63.4% (FU; P<0.0001), with reduced LVEF noted in 26.2% at FU<90%BL, in 13.5% at FU<BL–10%, and in 5.7% at LVEF<53%. A significantly greater percentage of patients with CTRCD (FU<BL–10% and LVEF<53%) had cardiovascular risk factors (CVRF; 42.9% vs. 8.2%, P=0.02). On multivariable analysis, CVRF were also significantly associated with CTRCD (OR, 11.96; 95% CI: 1.30–110.34).

**Conclusions:** Adjuvant trastuzumab for early-stage breast cancer was associated with reduced LVEF; and CVRF were an independent predictor for CTRCD. The concomitant effect of anthracyclines should not be underestimated, even at lower doses.

**Key Words:** Breast cancer; Cancer treatment-related cardiovascular disorder; Cardio-oncology; Cardiovascular risk factor; Trastuzumab

Progress in medical care for cancer has greatly contributed to lower mortality rates in affected patients, resulting in the increasing importance of cancer survivorship care in Japan and throughout the world. Epidemiological studies indicate that one of the most important causes of death in cancer survivors is cardiovascular disease (CVD). In addition to common risk factors for CVD and cancer, there is also growing awareness of cancer treatment-related cardiovascular disorders (CTRCD) associated with traditional and modern treatment strategies.

Cardio-oncology is a rapidly developing field in which cardiologists and oncologists collaborate to deal with novel issues including CTRCD, with a common goal of improving the prognosis of cancer patients. The compelling clinical need for cardio-oncology services was initially recognized by major educational hospitals, then those efforts gradually developed into national and academic collaborations to conduct research, resulting in publication of important findings and evidence-based clinical practice guidelines. Trastuzumab, one of the first available molecular targeted therapies, has been found to significantly improve the prognosis of human epidermal growth factor receptor-2...
(HER2)-positive breast cancer.\textsuperscript{17–19} It was initially approved for the treatment of metastatic disease,\textsuperscript{17} and subsequently for adjuvant chemotherapy for early-stage breast cancer.\textsuperscript{18} Cardiotoxicity was also identified in clinical trials, especially in patients receiving concurrent anthracyclines, and a warning has been included prominently on the label since approval was obtained for use.\textsuperscript{20} The process of developing cardio-oncology guidelines highlighted the lack of uniformity of cardiac assessment during trastuzumab therapy.\textsuperscript{21} For example, some oncology guidelines that distinguish trastuzumab from anthracycline cardiotoxicity do not recommend excessive monitoring to avoid unnecessary discontinuation of cancer treatment.\textsuperscript{22} In contrast, most cardiology guidelines recommend routine monitoring of biomarkers and imaging to detect asymptomatic cardiac dysfunction rather than waiting for symptomatic heart failure onset.\textsuperscript{23} In other words, insufficient data are available to identify high-risk patients as well as high-risk treatments for CTRCD in this new field of interdisciplinary research, demonstrating an urgent need for clinical evidence with which to develop risk scores\textsuperscript{24} and validate surrogate markers.\textsuperscript{25}

The aim of the present study was therefore to provide real-world data from a cardio-oncology viewpoint regarding risk profiling and the cardiac assessment of patients with breast cancer in Japan who are receiving adjuvant trastuzumab.

**Methods**

**Subjects**

The study flow chart is shown in Figure 1. A total of 216 consecutive female patients with HER2-positive breast cancer undergoing adjuvant trastuzumab therapy at Juntendo University Hospital (Tokyo, Japan) between April 2010 and December 2016 were retrospectively identified from hospital records. Those without baseline (BL) echocardiography (n=4), without follow-up (FU) for left ventricular ejection fraction (LVEF; n=67), with <90 days of trastuzumab therapy (n=2), and who were lost to FU (n=2) were excluded from analysis.

**Data Collection**

BL information collected from the medical records included age, body mass index (BMI), cardiovascular risk factors (CVRF; i.e., hypertension, diabetes, dyslipidemia, CVD), and details regarding cancer treatment (i.e., concurrent chemotherapy regimens, surgery, radiation therapy).

The protocol for this retrospective study was designed in accordance with the Declaration of Helsinki and the Ethics Guidelines for Clinical Research of the Ministry of Health, Labour, and Welfare of Japan, and received approval from the Juntendo University Hospital Ethics Committee (17-271). Informed consent was not required because this was an observational study with an opportunity to opt out. All patient data were anonymized prior to statistical analysis.

**Cardiac Assessment**

LVEF measurements (modified Simpson’s method) were performed at BL (minimum LVEF before trastuzumab therapy) and at FU (minimum LVEF after trastuzumab treatment).

**LV Dysfunction and CTRCD**

Of several proposed criteria for LV dysfunction,\textsuperscript{26} 3 thresholds for LVEF were evaluated in the present study as follows: A, 10% relative decrease from BL (FU<90% BL); B, absolute decrease of 10% from BL (FU<BL–10%); and C, decrease to below institutional normal (LVEF<53%). For the present analyses, CTRCD was defined according to a previous consensus statement (B and C).\textsuperscript{23}

**Statistical Analysis**

Continuous variables are expressed as mean±SD or median (IQR), and were compared using Student’s t-test or Wilcoxon rank sum test. Categorical variables are expressed...
as percentage or frequency, and were compared using Fisher’s exact test or chi-squared test. Logistic regression analysis was used to compare odds ratios (OR) and 95% CI. Age, anthracycline use, radiotherapy, and BMI were selected as covariates for multivariate analysis. Probability values are 2-tailed and P<0.05 was considered to indicate statistical significance. All analyses were performed using SAS ver. 9.4 (SAS Institute, Cary, NC, USA).

Results

Subjects

The present analysis involved 141 female patients with HER2-positive breast cancer who underwent adjuvant trastuzumab therapy. Their BL clinical features are listed in Table 1. Mean age was 54 years and the median duration of trastuzumab therapy was 11.0 months (IQR, 10.7–13.3 months). The majority (94.3%) of these patients received anthracycline chemotherapy in addition to trastuzumab, while approximately half (53.2%) underwent radiation therapy and were analyzed according to the site of irradiation.

Cardiac Assessment and Clinical Outcome

LVEF was significantly lower at FU as compared with BL (63.4%; IQR, 58.2–68.5% vs. 67.5%, IQR, 64.4–70.5%, P<0.0001; Figure 2). Detailed analysis of the threshold for LV dysfunction is shown in Figure 3. The numbers of CTRCD patients with A, 10% relative LVEF decrease from BL (FU<BL–10%); B, absolute LVEF decrease of 10% from BL (FU<BL–10%); and C, LVEF decrease to below institutional normal (LVEF <53%); and that of B and C combined were 37 (26.2%), 19 (13.5%), 8 (5.7%), and 7 (5.0%), respectively. Twenty-two patients (15.6%) underwent consultation with a cardiologist; and discontinuation of trastuzumab treatment due to CTRCD was noted in 3 (2.1%). During the FU period, none of the patients died of a tumor-related cause and no cardiac deaths were observed.

CTRCD Risk Profiling

Patients were subdivided into CTRCD(+) (n=7) and CTRCD(–) (n=134) groups (Table 2). There were no differences in regard to duration of trastuzumab or of combination therapy, or BMI between those groups. In contrast, there was a significant difference in regard to age between patients with and without CTRCD (63.4±10.7 vs. 53.9±11.4 years, P=0.04), and with and without CVRF (42.9% vs. 8.2%, P=0.02). On multivariate analysis, CVRF at BL independently predicted subsequent development of CTRCD (OR, 11.96; 95% CI: 1.30–110.3; Table 3). The relationship between LVEF change (BL–FU) and CVRF is shown in Figure 4.

Discussion

In this retrospective observational study of 141 consecutive female patients with early-stage breast cancer who underwent trastuzumab therapy in Japan, we found 3 cases (2.1%) of cancer treatment discontinuation in 7 patients (5.0%) who developed CTRCD. The incidence of CTRCD, defined as LVEF FU<BL–10% and LVEF <53%, was similar to previous reports. CVRF (hypertension, diabetes, dyslipidemia, or history of heart disease) as well as age have been identified as predictors of CTRCD. The effects of anthracyclines, even in lower doses, have not been ruled out. The present findings show that even in Japan or Asia, where the incidence of heart disease is considered to be lower than that in the USA and Europe, there is a significant number of types of asymptomatic LV dysfunction as well as a small but important number of types of symptomatic heart failure, which can potentially worsen the prognosis of cancer survivors.

The present results are consistent with recent trends in cardio-oncology research. Immediately after the introduction of molecular targeted drugs, cardiotoxicity was classified into type I (irreversible) and type II (reversible), although increasing evidence suggests that this classification is incomplete and inaccurate. First, because heart failure is a progressive condition from stage A (risk), to stage B (asymptomatic) and then stage C/D (symptomatic), it cannot be classified by the type of drug treatment alone. Second, although trastuzumab toxicity has been shown to be the second most common type of cardiotoxicity, the classification of cardiotoxicity can no longer be limited to 2 types following the introduction of a wide variety of cancer treatments. Thus, in clinical practice, trastuzumab cardiotoxicity should not be considered reversible.
it is important to identify high-risk patients and high-risk treatments before initiation of cancer treatment, followed by monitoring during treatment and during FU sessions after treatment, depending on the individual risk status.\textsuperscript{16}

Significant progress has been made in breast cancer treatment options, such as trastuzumab therapy, and the importance of cardiologists in a team-based approach has been noted.\textsuperscript{36} CVD is the second most common cause of death and in some subgroups, such as postmenopausal women with hormone receptor positive (HR+) breast cancer, death from CVD is more common than from cancer.\textsuperscript{4} Additionally, there are common risk factors shared by breast cancer and CVD, such as smoking, family history, and obesity.\textsuperscript{37} The present results indicate the importance of CVRF in addition to chemotherapy, molecular and endocrine therapy, and radiation therapy for patients with breast cancer. Prevention and management of CVD by cardiologists is expected to support completion of optimal cancer treatment, thus improving overall survival with the use of a team-based approach.\textsuperscript{16}
Although trastuzumab was one of the first molecular targeted treatments approved for cancer treatment, the mechanism related to its cardiotoxicity is not well understood.\textsuperscript{38} The drug is a monoclonal antibody that binds to HER2 and decreases its signaling. Intensive benefit–risk analyses of trastuzumab have been performed in basic as well as clinical research studies. Addition of trastuzumab to standard chemotherapy has been shown to improve the outcomes of metastatic as well as of early-stage HER2-positive breast cancer.\textsuperscript{17,18} Especially, for patients with early-stage disease in whom the goal is cure, systemic chemotherapy given before (neoadjuvant) or after (adjuvant) surgery is critically important to eradicate micrometastatic disease and decrease the risk of recurrence.\textsuperscript{36} In our experience, the clinically most important side-effect preventing completion of trastuzumab treatment for early-stage breast cancer is cardiotoxicity, which results in various conditions from asymptomatic myocardial damage to development of symptomatic heart failure. Neuregulin-1 (NRG-1) is an essential protein in adult myocardium tissues for cell cycle survival, because it promotes sarcomere stability and reduces oxidative stress. HER2 binds with NRG-1 to maintain cell survival and stabilizes signals that prevent apoptosis in response to stress, while trastuzumab is considered to block these pathways by inhibiting the HER2 receptor.\textsuperscript{38} Further elucidation of the pathophysiological factors is necessary for prevention, diagnosis, and treatment of trastuzumab cardiotoxicity.\textsuperscript{39}

### Table 2. Risk Profiling of CTRCD

| Patient demographics | \( (+)(n=7) \) | \( (-)(n=134) \) | \( P \)-value |
|----------------------|----------------|---------------|-------------|
| Age (years)          | 63.0±10.7      | 53.5±11.4     | 0.04        |
| Age >65              | 4 (57.1)       | 23 (17.2)     |             |
| BMI (kg/m\(^2\))     | 20±2.0         | 22±3.3        | 0.13        |
| Underweight (\(<18.4\)) | 2 (28.6)   | 20 (14.9)     |             |
| Normal (18.5–24.9)   | 5 (71.4)       | 85 (63.4)     |             |
| Overweight (25.0–29.9) | 0 (0.0)     | 27 (20.2)     |             |
| Obese (\(\geq30.0\)) | 0 (0.0)    | 2 (1.5)       |             |
| CVRF                 | 3 (42.9)       | 11 (8.2)      | 0.02        |
| Hypertension         | 3 (42.9)       | 5 (3.7)       |             |
| Diabetes mellitus    | 0 (0.0)        | 3 (2.2)       |             |
| Hypercholesterolemia | 1 (14.3)       | 9 (6.7)       |             |
| Cardiac disease      | 1 (14.3)       | 0 (0.0)       |             |

### Table 3. Multivariate Indicators of CTRCD

| OR          | 95\% CI       |
|-------------|---------------|
| CVRF        | 11.968        | 1.298–110.34  |
| Age (years) | 1.054         | 0.971–1.145   |
| Dose (anthracycline) | 1.001        | 0.990–1.012   |
| Radiotherapy | 0.519        | 0.084–3.230   |
| BMI         | 0.710         | 0.495–1.018   |

Data given as \( n(\%) \), mean±SD or median (IQR). Endocrine treatment includes aromatase inhibitors (anastrozole, letrozole), selective estrogen receptor modulator (tamoxifen), and GnRH agonist (goserelin). CTRCD, cancer treatment-related cardiovascular disorders; LVEF, left ventricular ejection fraction. Other abbreviations as in Table 1.
oncologists with the common goal of maximizing the outcome of cancer treatment while minimizing the risk of CVD. Although initially thought to be due to oxidative stress, pathological conditions at the molecular cell level have been clarified in recent years, although additional research as well as development of cardioprotective drugs are needed. Radiation therapy, especially for left breast cancer with cardiac radiation, is known to be associated with cardiovascular adverse events, while recent technological advancements have reduced the incidence of radiation-induced CVD. Additionally, new therapies, such as molecular targeted drugs and immune checkpoint inhibitors, have been approved, with CTRCD, a completely new pathophysiology, also emerging. For example, vascular endothelial growth factor inhibitors such as bevacizumab for colorectal cancer, and proteasome inhibitors such as bortezomib for multiple myeloma, as well as immune checkpoint inhibitors such as nivolumab for malignant melanoma and pembrolizumab for lung cancer have been shown to be effective. However, many new CTRCD for the aforementioned conditions, such as cardiac dysfunction, coronary artery disease, peripheral artery disease, arrhythmia, hypertension, valvular disease, and venous thromboembolism, have never been encountered by the majority of cardiologists. Therefore, there is a compelling need for a new interdisciplinary area of cardio-oncology, in which oncologists and cardiologists collaborate for the better understanding of treatment options.

Cardio-oncology as well as onco-cardiology represent a patient-centered collaboration between cardiologists and oncologists with the common goal of maximizing the outcome of cancer treatment while minimizing the risk of CVD. Each started as a team-based approach by healthcare providers to dealing with cardiotoxicity related to anthracycline or radiation therapy. Subsequently, the necessity of basic, clinical, and epidemiological research has been examined as a response at both national and academic levels. These public–private partnerships have led to a dramatic increase in competitive research funds and published papers. Presently, discussions are underway to build a sustainable system, involving the creation of clinical guidelines and input regarding medical insurance reimbursement.

Information regarding CTRCD has been available for some time. For example, anthracyclines have been known to be associated with severe and irreversible heart failure since the 1970s, and attention must be given to cumulative dose over the lifetime of a treated patient. Although initially thought to be due to oxidative stress, pathological conditions at the molecular cell level have been clarified in recent years, although additional research as well as development of cardioprotective drugs are needed. Radiation therapy, especially for left breast cancer with cardiac radiation, is known to be associated with cardiovascular adverse events, while recent technological advancements have reduced the incidence of radiation-induced CVD. Additionally, new therapies, such as molecular targeted drugs and immune checkpoint inhibitors, have been approved, with CTRCD, a completely new pathophysiology, also emerging. For example, vascular endothelial growth factor inhibitors such as bevacizumab for colorectal cancer, and proteasome inhibitors such as bortezomib for multiple myeloma, as well as immune checkpoint inhibitors such as nivolumab for malignant melanoma and pembrolizumab for lung cancer have been shown to be effective. However, many new CTRCD for the aforementioned conditions, such as cardiac dysfunction, coronary artery disease, peripheral artery disease, arrhythmia, hypertension, valvular disease, and venous thromboembolism, have never been encountered by the majority of cardiologists. Therefore, there is a compelling need for a new interdisciplinary area of cardio-oncology, in which oncologists and cardiologists collaborate for the better understanding of treatment options.

Cardio-oncology as well as onco-cardiology represent a patient-centered collaboration between cardiologists and oncologists with the common goal of maximizing the outcome of cancer treatment while minimizing the risk of CVD. Each started as a team-based approach by healthcare providers to dealing with cardiotoxicity related to anthracycline or radiation therapy. Subsequently, the necessity of basic, clinical, and epidemiological research has been examined as a response at both national and academic levels. These public–private partnerships have led to a dramatic increase in competitive research funds and published papers. Presently, discussions are underway to build a sustainable system, involving the creation of clinical guidelines and input regarding medical insurance reimbursement.

Cardiac assessment during and after cancer treatment is expected to improve prevention, diagnosis, and treatment of symptomatic CTRCD, and also help to avoid discontinuation of cancer treatment. Although the present retrospective observational study suggests that monitoring LVEF, as specified in the trastuzumab package insert, is important for diagnosis of CTRCD, it may not be sufficient for prevention. Currently, there are ongoing investigations to quantify LVEF for early detection of CTRCD using a variety of techniques, including 2-D and 3-D echocardiography, global longitudinal strain, tissue Doppler imaging, multigated acquisition scanning, and cardiac magnetic resonance imaging. Additionally, biomarkers including B-type natriuretic peptide, cardiac troponins, and others are also being studied. From a cardio-oncology perspective, there is urgent need to validate surrogate endpoints for both positive and negative predictive values based on sensitivity, specificity, and cut-offs, in order to encourage early detection of CTRCD while avoiding premature termination of therapy due to overdiagnosis.
Study Limitations
There were some limitations associated with this retrospective, single-center observational study conducted at a Japanese educational hospital. First, there are potential confounding factors, biases, and missing values. For example, not all of the pre-treatment CVRF have been adjudicated by cardiologists. In addition, the study design did not have sufficient statistical power to rule out the influence of concomitant therapies including irradiation site and anthracycline therapy. Therefore, causal relationships between treatment strategy, CVRF, and CTRCD must be carefully interpreted. Second, attention should be paid to the characteristics of the hospital. Of the 216 patients screened in this study, only 4 did not have BL LVEF measurements available. However, real-world data show gaps between guidelines and actual clinical practice. Therefore, additional investigations are needed regarding the incidence and prognosis of CTRCD in situations in which cardiovascular monitoring is less frequently used. Third, although we used LVEF to evaluate CTRCD in this study, there are known issues, including sensitivity, specificity, and reproducibility, related to the use of 2-D echocardiography as a tool to detect CTRCD. Nevertheless, it is important to note that there are ongoing investigations to validate various imaging modalities as well as examinations of biomarkers before, during, and after high-risk treatment for high-risk patients in order to minimize CTRCD and maximize the outcome of cancer treatment. Finally, with regard to ethnicity factors, heart disease is known to have a lower prevalence in Japan and in Asia as compared with Western populations due to both genetic and environmental factors, although it is showing an increasing trend along with economic development. A future investigation is needed to determine whether a similar trend exists for CTRCD.

Conclusions
Although this retrospective analysis indicates an increased prevalence of CTRCD in patients with potentially modifiable CVRF who underwent adjuvant trastuzumab therapy, there are multiple factors to be considered before, during, and after cancer treatment for prevention, diagnosis, and treatment of cardiovascular comorbidities. Development of CTRCD disrupts the risk–benefit balance for patients with early-stage cancer, emphasizing the need for additional studies to identify at-risk populations, validate monitoring strategies, and establish evidence-based clinical practice guidelines for the field of cardio-oncology.
