Summary

More than 50 interventions have been used to treat hidradenitis suppurativa (HS), and so therapy decisions can be challenging. Our objective was to summarize and appraise randomized controlled trial (RCT) evidence for HS interventions in adults. Searches were conducted in Medline, Embase, CENTRAL, LILACS, five trials registers and abstracts from eight dermatology conferences until 13 August 2015. Two review authors independently assessed study eligibility, extracted data and assessed methodological quality. Primary outcomes were quality of life and adverse effects of the interventions. Twelve trials, from 1983 to 2015, investigating 15 different interventions met our inclusion criteria. The median trial duration was 16 weeks and the median number of participants was 27. Adalimumab 40 mg weekly improved the Dermatology Life Quality Index (DLQI) by 4.0 points, which equates to the minimal clinically important difference for the scale, compared with placebo (95% confidence interval −6.5 to −1.5 points). Evidence quality was reduced to ‘moderate’ because the results are based on only a single study. Adalimumab 40 mg every other week was ineffective in a meta-analysis of two studies comprising 124 participants. Infliximab 5 mg kg⁻¹ improved the DLQI score by 8.4 points after 8 weeks in a moderate-quality study completed by 33 of 38 participants. Etanercept 50 mg twice weekly was ineffective. Inclusion of a gentamicin sponge prior to primary closure did not improve outcomes. Other interventions, including topical and oral antibiotics, were investigated by relatively small studies, preventing treatment recommendations due to imprecision. More, larger RCTs are required to investigate most HS interventions, particularly oral treatments and surgical therapy. Moderate-quality evidence suggests that adalimumab given weekly and infliximab are effective, whereas adalimumab every other week is ineffective.

Hidradenitis suppurativa (HS), also known as acne inversa, is a chronic inflammatory skin disease characterized by painful nodules, sinuses and scarring in flexural locations. Treatment of HS can be challenging, and more than 50 interventions have been reported in the literature, often supported by only low-quality evidence. As a result, it can be difficult for clinicians to make evidence-based decisions in partnership with patients.

In 2011 a Cochrane review team was assembled to undertake a review of all medical and surgical interventions for HS, restricting the systematic search for trial data to only the highest-quality evidence, in the form of randomized controlled trials (RCTs). The quality of the RCTs was also assessed using Grading of Recommendations Assessment, Development and Evaluation (GRADE) methodology, incorporated into summary of findings tables. The GRADE system evaluates the trial data for a particular intervention in terms of each key outcome pre-determined by the review team, and can be used to convert evidence quality and effect sizes into strengths of recommendations. The full review was recently published in the Cochrane Library and is summarized here.3

Methods

The protocol for our Cochrane review was pre-published in the Cochrane Library, and any deviations from the protocol are highlighted in the final published review.3 Our inclusion criteria to select relevant studies were RCTs of any HS intervention involving male and female adults of any age and ethnicity. Only the first phase of crossover trials was included to avoid carry-over effects of interventions with a long duration of action. Primary and secondary outcomes are given in Table 1 and were selected following discussion between the clinicians and consumer author on the review team. In keeping with Cochrane guidelines,4 one primary outcome was selected to assess treatment benefit, namely quality of life, and one to assess potential harm, in this case the adverse effects of interventions. Adverse effects were defined as serious if they resulted in death, hospital admission or a longer hospital stay.

Search strategies

Using the terms ‘acne inversa’, ‘hidradenitis suppurativa’, ‘velpeau’ or ‘verneuil’, we searched for RCTs in the following databases from inception until 13 August 2015: Cochrane Skin Group Specialised Register, Cochrane Central Register of Controlled Trials (CENTRAL), Medline, Embase and LILACS. We also searched five trials registers, namely the metaRegister of Controlled Trials (http://www.isrctn.com/page/mrct), the US National Institutes of Health Ongoing Trials Register (www.clinicaltrials.gov), the Australian New Zealand Clinical Trials Registry (www.anzctr.org.au), the World Health Organization International Clinical Trials Registry platform (www.who.int/trialsearch) and the EU Clinical Trials Register (https://www.clinicaltrialregister.eu). In addition, hand searching of the abstracts from eight international dermatology conferences was undertaken, and bibliographies from both included and excluded studies were examined. Two authors (J.R.I. and A.C.K.) independently undertook study selection and no language restrictions were applied.

Data extraction and analysis

Following piloting of our data extraction form, two pairs of authors (J.R.I. and either P.N.W., S.L.C. or A.D.O.) independently extracted data from the included studies and made an assessment of methodological study quality using a Cochrane ‘risk of bias’ tool.4 The GRADE profiler (GRADEpro) was then used to assess evidence quality for each review outcome.2 Using GRADE, evidence quality is downgraded from ‘high quality’ by one level for each serious issue identified in the domains of risk of bias, imprecision, indirectness, inconsistency and publication bias.
Dichotomous outcome measures were expressed as risk ratios and continuous outcomes were reported as mean differences. Side-to-side, within-participant trials of topical therapies were permitted provided that a systemic effect was unlikely and that the left and right sides of the same anatomical site were compared, because different sites may respond differently to particular interventions. Statistical heterogeneity was assessed using the I² statistic. We used a fixed-effects model for I² values < 40% and a random-effects model for values between 40% and 75% (there were no I² values > 75%).

Results

Description of the included studies

Our searches identified 12 trials for inclusion in the review (Fig. 1), in which a total of 615 adults with HS participated.5–16 The 12 trials investigated 15 different interventions and most were relatively small, with a median number of participants of 27. In terms of trial design, eight were parallel-group studies,5–8,10,12–14 three were within-participant trials,9,11,16 and one was a crossover study for which we included only the first-phase data because carry-over effects were likely.15 The median trial duration was 16 weeks.

We divided the interventions into topical therapy, systemic therapy, surgical treatment and other therapies. Antitumour necrosis factor-α therapies were investigated in four studies,5,10,13,14 and are classified as a subgroup of systemic therapy.

Risk of bias in the included studies

The risk of bias for each domain across all included studies is given in Figure 2. There was a high risk of performance bias for within-participant laser and light studies that did not employ a sham intervention on the untreated side.9,11,16 Detection bias was avoided for investigator-reported outcomes in these studies by using assessors who were blinded to treatment allocation; however, participant-reported outcomes remained at high risk of bias. Two studies were at high risk of attrition bias due to an attrition rate > 20% and lack of an intention-to-treat analysis.12,16
Effects of interventions

Data for the effects of interventions and the evidence quality assessed using GRADE methodology are presented in the summary of findings tables (Tables 2–4 and Tables S1–9).

Topical therapies

Topical clindamycin vs. placebo A single trial of 30 participants compared clindamycin 1% solution with vehicle solution for 12 weeks (frequency of application unstated).8 There was no difference in adverse effects between the two groups, which were reported to be mild (Table S1). SDs for the study efficacy data were unavailable, preventing inclusion in the summary of findings table, and a quality-of-life outcome was not measured. Regarding the available efficacy outcomes, there was no difference in participant self-assessment scores between the two groups. However, there was a significant improvement in the HS score, a composite scale incorporating the Participant’s Global Assessment and the number of inflammatory nodules, abscesses and pustules, in favour of topical clindamycin.

Systemic therapies

Oral tetracycline vs. topical clindamycin Forty-six participants with mild-to-moderate HS were randomized to receive either oral tetracycline 500 mg twice daily and vehicle solution or oral placebo and clindamycin 1% solution for 16 weeks.12 Quality of life was not measured, but oral tetracycline did produce a statistically significant improvement in Participant’s Global Assessment compared with topical clindamycin (Table S2). There was no difference in pain, number of HS lesions or Physician’s Global Assessment. Three adverse events occurred in the tetracycline group and five events in the topical clindamycin group, but the type and severity of events were not recorded. Quality of evidence was downgraded to ‘low’ due to attrition bias, because 12 participants did not complete the study and were unaccounted for, and because of imprecision from a single small study.

Ethinylestradiol and cyproterone acetate vs. ethinylestradiol and norgestrel A 12-month crossover study of 24 female participants with moderate-to-severe HS compared ethinylestradiol 50 μg and norgestrel 500 μg daily on days 5–25 of each menstrual cycle with ethinylestradiol 50 μg and cyproterone acetate 50 mg on days 5–14 of each cycle.15 We included efficacy data up to the 6-month crossover point and there was no significant difference in Participant’s Global Assessment (Table S3). Only 18 participants completed the study, and thus the evidence quality was reduced to ‘moderate’ due to imprecision.

Systemic therapies: antitumour necrosis factor-α therapies

Etanercept vs. placebo Twenty participants with active HS were randomized to subcutaneous etanercept 50 mg twice weekly or placebo injections for 12 weeks.3 The study reported P-values without original trial data, and from the P-values there were no differences between the two groups at 12 weeks in Dermatology Life Quality Index (DLQI) scores (Table S4), Participant’s Global Assessment, pain or Physician’s Global Assessment. There were no serious adverse events reported, only mild injection-site reactions.

Adalimumab weekly vs. placebo One of the three arms of a placebo-controlled trial of adalimumab therapy investigated a subcutaneous dose of 40 mg weekly from weeks 4 to 15, following loading doses of 160 mg at week 0 and 80 mg at week 2.13 Fifty-one participants received weekly adalimumab and 51 were given placebo injections. The results were presented using both last-observation-carried-forward (LOCF) and imputation methods for handling missing data. At 16 weeks, adalimumab weekly improved the DLQI score by 40 points compared with placebo [95% confidence interval (CI) −6·49 to −1·51, imputation method] (Table 2). Comparing the two groups, there was no significant difference in serious adverse events [relative risk (RR) 2·00, 95% CI 0·38–10·44] or infectious adverse events (RR 0·94, 95% CI 0·55–1·62) (Table 2). Adalimumab weekly was superior to placebo for nearly all of our other secondary outcomes, as well as the economic outcome Total Work Productivity Impairment score [mean difference (MD) −19·50, 95% CI −30·07 to −8·93, imputation method]. The study was assessed to be at low risk of bias for all domains, but the evidence quality was reduced to ‘moderate’ because it is based on only a single study and subsequent

studies are likely to impact on our confidence in the effect estimate and may change the estimate. 17

Adalimumab every other week vs. placebo A meta-analysis of two studies was possible for several outcomes in this comparison. Another of the three arms of the RCT described above compared 52 participants given subcutaneous adalimumab 40 mg every other week (EOW), following loading doses of 80 mg at week 0 and 40 mg at week 1, with 51 participants given placebo injections, reporting primary outcomes at week 16. 13 A smaller study compared 15 participants given adalimumab 40 mg EOW with six participants who received placebo injections, with primary outcomes measured after 12 weeks. 14 From the meta-analysis (Table 3) there was no statistically significant difference between adalimumab EOW and placebo for change in DLQI score (MD −1.61, 95% CI −3.86 to 0.64). There was also no difference in the secondary outcomes of pain, HS lesion score, Physician’s Global Assessment and Total Work Productivity Impairment.

Infliximab vs. placebo One RCT of 38 participants, of whom 33 completed the trial, compared intravenous infliximab 5 mg kg−1 with intravenous placebo, reporting primary outcomes at week 8. 10 Infliximab was given in the standard dosing regimen, at weeks 0, 2 and 6. Infliximab improved the DLQI score relative to placebo, with an effect size of 23 lower (MD = −6.64, 95% CI −13.98 to 0.70, 96 (1 study) ⊕⊕⊕⊝ moderate). There was also no difference in the secondary outcomes of pain, HS lesion score, Physician’s Global Assessment and Total Work Productivity Impairment.

Adalimumab every other week vs. placebo A meta-analysis of two studies was possible for several outcomes in this comparison. improved pain and Physician’s Global Assessment relative to placebo, but there was no significant difference in the proportion of participants in the two groups achieving ≥ 50% improvement in an unvalidated ‘HS Severity Index’ score. The evidence quality was downgraded to ‘moderate’ because of the imprecision resulting from a single, relatively small study.

| Outcomes                                      | Assumed risk | Corresponding risk | Relative effect (95% CI) | Number of participants (studies) | Quality of evidence (GRADE) | Comments |

CI, confidence interval; DLQI, Dermatology Life Quality Index; LOCF, last-observation-carried-forward; RR, risk ratio; SMD, standardized mean difference; VAS, visual analogue scale. GRADE Working Group grades of evidence: High quality, further research is very unlikely to change our confidence in the estimate of effect; moderate quality, further research is likely to have an important impact on our confidence in the estimate of effect and may change the estimate; low quality, further research is very likely to have an important impact on our confidence in the estimate of effect and is likely to change the estimate; very low quality, we are very uncertain about the estimate. The basis for the assumed risk is the mean risk in the placebo groups of the study populations. The corresponding risk (and its 95% CI) is based on the assumed risk in the comparison group and the relative effect of the intervention (and its 95% CI). Follow-up 12 weeks for 21 participants. Imbalance in baseline disease severity between the two groups: downgraded due to indirectness as the results may not be of relevance to the wider population. Downgraded one level for imprecision because the evidence is based on the results of a single study (for each of these outcomes) and subsequent studies are likely to have an important impact on our confidence in the estimate of effect and may change the estimate. Downgraded one level for inconsistency as the I² statistic of 59% demonstrates substantial study heterogeneity for this outcome.
Table 4 Summary of findings: infliximab compared with placebo for hidradenitis suppurativa (HS). Patient or population: participants with HS.
Setting: hospital based. Intervention: infliximab. Comparison: placebo

\(^a\) CI, confidence interval; RR, risk ratio. GRADE Working Group grades of evidence: high quality, further research is very unlikely to change our confidence in the estimate of effect; moderate quality, further research is likely to have an important impact on our confidence in the estimate of effect and may change the estimate; low quality, further research is very likely to have an important impact on our confidence in the estimate of effect and is likely to change the estimate; very low quality, we are very uncertain about the estimate. \(^b\) The assumed risk is the risk in the placebo group of the study population. The corresponding risk (and its 95% CI) is based on the assumed risk in the comparison group and the relative effect of the intervention (and its 95% CI). \(^c\) Downgraded one level for imprecision due to a small number of events in only a single study.

Surgical interventions

Gentamicin sponge vs. primary closure alone Two hundred participants with HS undergoing excision of symptomatic lesions were randomized to insertion of a gentamicin–collagen sponge prior to closure or primary closure alone.\(^7\) Assessment of surgical complications found no difference between the groups at week 1 (RR 0.78, 95% CI 0.58–1.05) or after 3 months (RR 0.90, 95% CI 0.50–1.62) (Table S5). The duration of remission, measured by the recurrence rate at 3 months, was not significantly altered by addition of the gentamicin sponge (RR 0.96, 95% CI 0.68–1.34). The evidence quality was downgraded to 'moderate' due to an unclear risk of bias in most domains, including an imbalance in randomization due to early study cessation.

Other interventions

Intense pulsed light vs. no treatment A within-participant trial randomized 17 participants to intense pulsed light treatment of one side of a bilaterally affected region, compared with no treatment of the other side.\(^11\) Twelve participants underwent treatment of the axilla, four had groin involvement and one had inframammary disease. Treatment-related pain caused one participant to withdraw (treatment site unknown). Participant treatment satisfaction was measured with an unvalidated Likert scale and we defined treatment success as ratings of good, excellent or clear compared with baseline. Overall, intense pulsed light provided better participant satisfaction than no treatment (RR 9.67, 95% CI 2.10–46.43) (Table S6); however, the evidence quality was downgraded to 'low' due to performance bias and imprecision.

Neodymium-doped yttrium aluminium garnet laser vs. topical control A trial of neodymium-doped yttrium aluminium garnet (Nd:YAG) laser therapy included 34 bilaterally affected anatomical sites in 22 participants.\(^16\) One side of each site was randomized to receive four laser treatments at monthly intervals, as well as topical antimicrobials, and the other side received topical antimicrobial therapy alone. At 3 months, results were available for 25 anatomical sites (11 groin, 10 axillary, four inframammary) in 17 participants. Forty per cent of participants reported laser-treatment-related pain, but none withdrew from the trial as a consequence. Using the modified HS Lesion, Area and Severity Index (HS-LASI) severity score, there was significant benefit from Nd:YAG laser therapy for all treated sites combined at 3 months (MD –14.03, 95% CI –18.84 to –9.22 points), and after a further 2 months of observation (Table S7).\(^18\) However, the evidence quality was downgraded to 'very low' due to the high risk of performance bias and attrition bias, and also imprecision.

Niosomal methylene blue gel photodynamic therapy vs. free methylene blue gel photodynamic therapy A within-participant trial compared niosomal methylene blue gel photodynamic therapy with free methylene blue gel photodynamic therapy given once every 2 weeks for up to 6 months.\(^9\) In the 10 participants who received treatment, niosomal methylene blue gel produced a significantly larger improvement in HS-LASI score than free methylene blue gel (MD –4.30, 95% CI –8.36 to –0.24) (Table S8). The evidence quality was downgraded to 'low' due to a high risk of performance bias and imprecision.

Staphage lysate vs. placebo broth Thirty-one participants were randomized to receive staphage lysate both subcutaneously and as an inhaled aerosol, or vehicle broth via the same administration routes, once weekly for 20 weeks.\(^6\) Staphage lysate is designed to induce an immunological response and was obtained by bacteriophage lysis of Staphylococcus aureus. No serious adverse events occurred in either group. Based on a
Physician’s Global Assessment grading of ‘improved’, staphage lysate was of greater benefit than placebo broth (RR 6·25, 95% CI 1·68–23·27) (Table S9). The evidence quality was downgraded to ‘moderate’ due to imprecision.

Discussion

Our review has highlighted a relative lack of high-quality evidence to guide treatment decisions in HS. Only 12 RCTs with a total of 615 participants met our inclusion criteria, whereas the recent Cochrane review update for vitiligo, a condition with a similar prevalence, contained 96 trials and 4512 participants. Many of the RCTs included in our HS review are small, with a median of 27 participants, and most interventions were investigated by only a single RCT. As a result, evidence quality had to be downgraded using GRADE methodology for most comparisons due to imprecision, limiting our clinical practice recommendations. For example, we did not find sufficient high-quality evidence to determine the effects of topical clindamycin or oral tetracycline, which are standard therapies for mild-to-moderate HS.

Four relatively recent RCTs of antitumour necrosis factor-α therapies included our primary outcome of quality of life. The results suggest that adalimumab 40 mg weekly improves quality of life compared with placebo, with a reduction in DLQI score of 4·0 points, which is equivalent to the minimal clinically important difference for the scale. However, the 95% CI includes an effect size of only 1·5 points, which may represent an insufficient clinical response. There was no significant difference in serious or infectious adverse effects compared with placebo, but any rare or delayed adverse effects of weekly adalimumab are currently unknown because psoriasis biological registers provide data only for EOW dosing. Another issue is the higher cost of weekly treatment compared with EOW therapy. The available evidence suggests that adalimumab EOW and etanercept 50 mg twice weekly are ineffective for HS. A single trial of infliximab providing efficacy data for 33 participants reported a DLQI reduction of 8·4 points relative to placebo, which is likely to be clinically relevant, but imprecision is a limiting factor due to the small number of participants.

Our review demonstrates a need for more surgical trials to improve HS care; in particular there are no RCTs investigating the timing of surgery or type of surgical procedure. We identified one trial of insertion of a gentamicin sponge wound-healing adjunct prior to primary closure, but this showed no benefit compared with primary closure alone.

Based on the RCT evidence available, laser and light therapies cannot be recommended for HS because the within-participant trial designs did not incorporate a sham intervention, which, combined with imprecision, led to downgrading of GRADE evidence quality. It is difficult to draw conclusions from the crossover trial investigating two endocrine interventions because of the small study size and lack of placebo control. Regarding staphage lysate, there have been no further trials since one small RCT was performed in 1987, resulting in insufficient evidence to recommend a change in practice.

The recent HS Priority Setting Partnership (PSP) ranked trials of oral therapies as the most important research priority, and our review has highlighted a lack of RCT evidence in this area, including an absence of RCTs investigating oral immunomodulators and retinoids, and only one RCT of oral antibiotic therapy. In line with HS PSP priorities, we found no trials investigating treatment of an acute flare or HS-associated pain management, and only one surgical trial. It will be important for the design of future trials to improve validation of HS outcome measures because many of the instruments employed by our included studies remain unvalidated and there is a lack of consensus regarding which outcomes to use.

There is hope for the future because our review identified eight ongoing HS RCTs in trial registers that have not yet been published in full. Interventions currently under investigation include topical antiseptics, the Nd:YAG and CO2 lasers, anaakinra, novel biological therapies, and the PIONEER I and II studies of adalimumab therapy. Results from these studies will be incorporated into the planned update to our review.
