Abstract

Investigations of the dynamics of the hot coronal plasma are crucial for understanding various space weather phenomena and making in-depth analyzes of the global heating of the solar corona. We present here numerical simulations of observations of siphon flows along loops (simple semi-circular flux ropes) to demonstrate the capabilities of the Solar Line Emission Dopplerometer (SLED), a new instrument under construction for imaging spectroscopy. It is based on the Multi-channel Subtractive Double Pass (MSDP) technique, which combines the advantages of filters and slit spectrographs. SLED will observe coronal structures in the forbidden lines of FeX 6374 Å and FeXIV 5303 Å, and will measure Doppler shifts up to 150 km s\textsuperscript{-1} at high precision (50 m s\textsuperscript{-1}) and cadence (1 Hz). It is optimized for studies of the dynamics of fast evolving events such as flares or Coronal Mass Ejections (CMEs), as well as for the detection of high-frequency waves. Observations will be performed with the coronagraph at Lomnický Štit Observatory (LSO), and will also occur during total solar eclipses as SLED is a portable instrument. © 2021 COSPAR. 1. Introduction

Solar activity is the primary driver of space weather events which develop over short timescales (minutes) in solar flares and CMEs. Such events are highly dynamic and originate in the solar atmosphere from magnetic energy stored in active regions, sunspots (Borrero & Ichimoto, 2011) and coronal loops (Reale, 2014). Hence, direct velocity measurements are crucial for understanding the physics of such phenomena. In cold layers (photosphere, chromosphere), Doppler observations are common; however, this is not the case at coronal temperatures.

The hot corona is imaged in the extreme ultraviolet (EUV) at 15 s maximum cadence by the Atmospheric Imaging Assembly (AIA) onboard the Solar Dynamics Observatory (SDO), at temperatures in the range 0.6 to 10.0 MK. STEREO and the Solar and Heliospheric Observatory (SOHO) use similar wavebands plus wide field, white light coronagraphs, while Solar Orbiter will soon offer EUV images. In parallel, ground-based coronagraphs provide observations at a much higher cadence, such as the SECIS instrument (Phillips et al., 2000), working in the green line of FeXIV 5303 Å. The corona has also been observed during total solar eclipses in visible emission lines (Rudawy et al., 2019), as well as infrared (IR) lines (Habbal et al., 2011).
Imaging instruments cannot measure plasma velocities, and for this tunable filters or spectrographs are required. LASCO/C1 onboard SOHO was able to scan the green (FeXIV) and red (FeX) lines with a Fabry Pérot filter (Brueckner et al., 1995). Mierla et al. (2008) studied velocities in the quiet corona, but it was not possible to access the velocities of fast events such as CMEs, due to the long time needed to scan the profiles. Singh et al. (2002) have characterized the coronal green (FeXIV 5303 Å) and red (FeX 6374 Å) emission lines using narrow slit spectroscopy. Spectra of the green line were also recorded by Sakurai et al. (2002). Livingston et al. (1980) and Singh et al. (1982) introduced multi-slit spectroscopy during the solar eclipse of 16 February 1980 to measure velocities. The Coronal Multi-channel Polarimeter (CoMP, Tomczyk et al. (2008)) is a ground-based instrument working in the IR lines of FeXIII (10747 Å and 10798 Å). CoMP can record velocities (and magnetic fields) with 15 s temporal resolution; it was used, for instance, to study Alfvén waves (Tomczyk et al., 2007) or the dynamics of CMEs (Tian et al., 2013).

The SLED instrument described in this paper will allow the measurement of line-of-sight (LOS) velocities in the coronal green and red lines, in a 2D field of view (FOV) and at high cadence (1 Hz), by combining the advantages of spectroscopy and tunable filters. Section 2 explains the principles of the imaging spectroscopy concept used by the SLED, while Section 3 summarizes the optical design. Section 4 presents the main scientific goals of the instrument and simulations of its capabilities are detailed in Section 5.

2. The Multichannel Subtractive Double Pass (MSDP) technique

SLED is a compact version of the MSDP imaging-spectrographs; the principle was first described by Mein (1977), and has been upgraded many times over the last decades on several telescopes (Mein et al., 2021). The layout of MSDP is shown in Figure 1 with a sample set of past observations. It is an imaging double pass spectrograph using a 2D rectangular entrance window (F1) and a slicer located in the focal plane of the spectrum (F2), after a first pass on the grating. The slicer selects N channels (beam-splitting) and realigns the N channels (beam-shifting) before the subtraction of the dispersion by the second pass on the grating. The output of the MSDP (F3) is composed of N contiguous spectra-images (N = 9 in Figure 1). There is a constant wavelength step between each spectra-image, but within each, the wavelength varies linearly along the x-direction. Data cubes (x, y, λ) of the whole FOV are extracted from a single exposure. Hence, the MSDP combines the advantages of filters and spectroscopy. The 2D FOV depends on the focal length of the telescope and the size of the window (F1), while the spectral resolution depends on the focal length of the spectrograph and the slicer parameters. The cadence is only limited by the photon flux and the detector speed.

The SLED/MSDP parameters are optimized for coronal lines (0.3 Å resolution), high velocities (N = 24), the size of active regions (150” × 1000” FOV) and time-scales involved in fast events or high-frequency waves (1 s).

3. The SLED optical design

The SLED has spectral resolution and wavelength range of respectively 0.28 Å and 6.5 Å (24 × 0.28 Å) for the FeXIV 5303 Å forbidden line. These parameters are convenient for coronal line widths (typically 0.8 Å FWHM) and large Doppler shifts (± 100 km s⁻¹ ≈ ± 2.0 Å).

The optical path of the SLED spectrograph is schematized in Figure 2, where the letters L and M refer to lenses and plane mirrors, respectively. The set of four lenses L1 to L4 acts as a collimator. Optimal components of the spectrograph are:

- F1: the rectangular entrance window (4.4 mm x 31.0 mm) located at the spectrograph focus.
- The first pass (light dispersion): F1, L1, M1, L2, M2, L3, L4, gratings, L4, L3, M2, L2, M1, L1, M3, slicer (F2).
- F2: 24 channels slicer located in the spectrum, made of 24 beam-splitting micro-mirrors and 24 associated beam-shifting mirrors.
- The second pass (subtractive dispersion): slicer (F2), M4, M5, L1, M1, L2, M2, L3, L4, gratings, L4, L3, M2, L2, M1, L1.
- The reduction optics to the detector: M6, field lens, M7 and camera lens (0.2 magnification).
- F3: the Andor Zyla camera (5.5 Mpixels sCMOS detector, 2560 × 2160 format, 6.5 micron square pixels) recording the 24 channel spectra-images with 2.1” spatial sampling.

The optical combination of four lenses (L1, L2, L3, L4) acts as a collimator (2.0 m equivalent focal length) with folding mirrors (M1, M2), while the grating is 62° blazed and 79 grooves/mm ruled. Orders are selected by filters (order 42 for FeXIV), and the resolution is R = 19000, with dispersion D = 1.43 mm/Å (for FeXIV). The wavelength sampling (0.28 Å) is the ratio S/D, where S = 0.4 mm is the micro-mirror step of the slicer. On exit, the camera lens (100 mm focal length) has a magnification factor of 0.2. More details are given in Mein et al. (2021).

There is a major difference between SLED/MSDP and conventional integral field spectrographs such as the GREGOR Infrared Spectrograph (GRIS, Vega Reyes et al. (2016)) and MuSICa for the future European Solar Telescope (Calcines et al., 2013). Specifically, SLED has a large variation of its spectral window coverage as a function of the FOV position in the direction parallel to the dispersion. In the centre of the FOV, the spectral range provided by the 24 channels is [-3.25 Å, +3.25 Å], corresponding to velocities up to 160 km s⁻¹. Towards the FOV edges, the spectral range keeps the same width (6.5 Å) but is shifted from [-4.8 Å, +1.7 Å] respectively from the left to the right side, where velocities up to 75 km s⁻¹ can still be determined. This 3.1 Å shift between both sides
is the ratio $W/D$, where $W = 4.4$ mm is the width of the 2D entrance window.

4. The scientific goals of the SLED

The SLED has two main goals owing to its capability to produce Dopplergrams at high temporal resolution.

4.1. Dynamic events of solar activity

SLED will observe the dynamics of coronal flux ropes and loops in active regions, flares, and CMEs, which drive solar-terrestrial interactions. It will study the plasma motions (Doppler shifts) inside hot structures (1 to 2 MK) at high cadence (1 Hz). These measurements could be combined with EUV intensities obtained at lower cadence by AIA onboard SDO in several lines emitted by plasma at temperatures in the range 0.6 to 10 MK. SLED will impose new constraints on models describing the dynamics of hot loops and their temporal evolution. The instrument will be available before the forthcoming solar maximum (cycle 25), when major events are expected to occur.

4.2. Coronal heating

Processes involved in the coronal heating are not yet fully understood (Klimchuk, 2006). The main plausible mechanisms fall into two categories: heating by numerous and concentrated magnetic reconnections (nano-flares), or the dissipation of Alfvén or MHD waves in coronal loops. Observations with CoMP (Tomczyk et al., 2007) revealed Alfvén-type wave motions of low frequency (peaking at 3.5 mHz) around active regions at the limb. However, their energy is too small to explain the heating, for which higher frequency waves are likely to be involved. Owing to telemetry limitations of satellites, a search for high-frequency waves was undertaken with ground-based instruments in fast imagery mode through narrow-band filters in the visible FeXIV or FeX lines. Samanta et al. (2016) searched for high frequency oscillations (0.1 Hz) using multi-slit spectroscopy of these two lines, observed simultaneously during the eclipse of 11 July 2010. Several campaigns were organized with SECIS (Rudawy et al. (2004), Rudawy et al. (2010), Rudawy et al. (2019)), but the short period fluctuations were questionable in terms of waves. For this reason, the SLED will investigate oscillations using Doppler measurements.

5. Simulation of the SLED capabilities

The core of the SLED is the 24 channel-slicer designed for F/30 beam. It is built for 0.20 m diameter/6.0 m equivalent focal length telescopes, such as the high-altitude Lomnický Štít Observatory (LSO) coronagraph (Lexa, 1963). However, the SLED will also be used for total eclipse observations, as it is a portable spectrograph. The FOV is compatible with the typical size of coronal active region loops ($10^8$ km).

In Figure the wavelength response of the 24 channels in terms of Doppler shifts (converted to velocities, positive for blue shifts) is displayed for the coronal green and red lines. The channels are not monochromatic, as the wavelength varies in the x-direction of the 2D FOV. Velocities up to 75 km s$^{-1}$ can be determined at all points in the FOV. However, velocities of the order of the local sound speed (150 km s$^{-1}$) can be measured near the FOV centre. For the green line, the maximum velocity is given by the relation $v_{\text{max}} = -1.17|x| + 163$ km s$^{-1}$ where $x$ is the abscissa ($) along the FOV. Hence, the SLED is ideally suited to observations of highly dynamic phenomena during solar activity.

In order to demonstrate the capabilities of the SLED to restore LOS velocities, we used the results of the simple model of Cargill & Priest (1980). It is a steady-state and adiabatic siphon flow in a semi-circular coronal magnetic loop with constant cross-section (see Figure 6a of their paper). They suggested several possible regimes, such as subsonic, transonic and supersonic flows with shocks (when the local Mach number exceeds unity). Assuming observations at the limb, we explored different view angles of the loop with respect to the line-of-sight, shown in Figure 4. The response of the SLED in terms of spectra images is simulated in Figure 5 in the case of a subsonic siphon flow observed in the FeXIV green line with a Gaussian profile of 0.8 Å FWHM.

From the SLED spectra image, such as that in Figure 6, we restored LOS velocities of subsonic and supersonic shocked flows seen through a rectangular 2D FOV either tangential or orthogonal to the limb. The SLED samples the line profiles with a 0.28 Å step by the transfer functions of Figure 3. We used a two-pass cubic interpolation to optimize the reconstruction of line profiles. LOS velocities were then computed using the bi-sector technique, in which we detect the middle position of a chord of 0.70 Å width, corresponding to the distance between the inflexion points. This choice minimizes errors in the velocity measurements. We found an excellent precision of 50 m s$^{-1}$ RMS, so that the SLED restorations of Figures 5 and 6 are indistinguishable from the LOS velocities of the input model. Table 1 shows the RMS interpolation error for different chords: it clearly indicates that inflexion points provide the best precision (the slope of the profiles is maximum there). We have also simulated the effect of the photon noise: it must be considered when the signal to noise ratio is smaller than about 100. We estimate (from SECIS extrapolation) that it should be 50 for the 1 Hz cadence necessary to study high frequency waves, and above 100 for moderate frame rates. Asymmetrical profiles can also affect the precision, for instance in the case of velocity gradients along the line of sight.

| Chord length (Å) | RMS error (km/s) |
|------------------|------------------|
| 0.56             | 0.25             |
| 0.63             | 0.11             |
| 0.70 (≈ IP)      | 0.05             |
| 0.77 (≈ FWHM)    | 0.17             |
| 0.84 (≈ FWHM)    | 0.23             |
Figure 4 shows the restoration of LOS velocities (using the inflexion points) in the case of high-speed supersonic shocked flows (M = 1.5) when the (long) y-direction of the rectangular FOV is orthogonal to the limb, for the various view angles of Figure 2. The curvilinear abscissa s along the flux rope is normalized to 1, and the shock is located at s = 0.7. SLED can measure LOS velocities up to the sound speed when the shocked region is close to the centre of the FOV in the x-direction. Within this orientation, the radius of the loop cannot exceed 55000 km (half-width of the FOV). Figure 7 displays the precision of the velocity restoration along the loop for 45° view angle; the best result is obtained when Doppler shifts are measured near the inflexion points of spectral lines. Oscillations correspond to interpolation errors occurring along the loop, because the sampling wavelengths of the profiles vary according to the LOS velocities and the x-abcissae in the FOV.

Alternatively, Figure 8 shows the restoration of LOS velocities when the (long) y-direction of the FOV is tangential to the limb, for the various angles of Figure 4. Within this orientation, the maximum radius of the loop is 110000 km (the width of the FOV). In the left panel of the figure, we used the subsonic model, so that LOS velocities are easily restored everywhere in the FOV. However, in the right panel, we used the supersonic shocked flow model (M = 1.5), and the highest LOS velocities, now close to the sides of the FOV, can no longer be properly recovered for all angles. Hence, the FOV orientation has to be considered when large radial velocities are suspected in coronal structures.

6. Conclusions

The Solar Line Emission Dopplerometer (SLED) is a new instrument for studies of the dynamics of coronal structures in the forbidden lines of FeX and FeXIV. Dopplergrams providing line-of-sight velocities will be delivered at high cadence (1 Hz) for a large FOV at the limb (150° × 1000°, 2.1″ pixel sampling). Plasma motions can be investigated during fast-evolving events such as flares or CMEs, and high-frequency oscillations relevant to coronal heating will be searched. Full line profiles (0.28 Å resolution) will be available everywhere in the 2D FOV, owing to an imaging spectroscopy technique which is faster than most tunable filters or slit spectrographs. However, the spectral window is not the same for different abcissae in the FOV, but has a constant width. SLED will complement spectroscopic instruments operating mainly in IR lines, such as CoMP or the future VELC onboard Aditya-L1 (Rai Kumar et al., 2018). It will monitor the coronal activity of cycle 25 at Lomnický Štít Observatory, but it could also observe total solar eclipses, such as the event of 8 April 2024 (North America).
