The finite size dependent enhancement of pairing in mesoscopic Fermi systems is studied under the assumption that the BCS approach is valid and that the two body force is size independent. Different systems are investigated such as superconducting metallic grains and films as well as atomic nuclei. It is shown that the finite size enhancement of pairing in these systems is in part due to the presence of a surface which accounts quite well for the data of nuclei and explains a good fraction of the enhancement in Al grains.

Since long it is a well-known fact that in certain finite size Fermi systems the gap is increased substantially from its bulk value. Such systems are, for instance, ultra small superconducting metallic grains, of great present actuality \[1\] \[2\] \[3\] but also superfluid atomic nuclei \[8\] \[9\]. There have been theoretical studies in the past on the size dependence of pairing in the abovementioned systems \[10\] \[11\] \[12\] \[13\]. To our knowledge for the condensed matter systems no satisfying explanation has been found \[12\] whereas for the nuclear systems large scale Hartree-Fock-Bogoliubov (HFB) calculations for nuclei have recently somewhat clarified the situation \[11\].

In this investigation we will set a rather limiting frame: we assume that BCS theory is valid and that the pairing force \(v(r)\) is size independent. These are, of course, very severe restrictions, and obviously, other size dependent features may be present in reality. We will consider simplified systems: First we study metallic grains and films in a hard wall potential using the standard schematic constant matrix element approximation with an adjustable strength parameter and a cut-off given by the Debye frequency. It will be shown that this model accounts for a good fraction of the experimental size dependence. Second we apply the previously developed pocket model \[1] \[2] \[3] \[12\] \[13\]. We, at first, will apply a statistical approach \[14\] \[15\]. This essentially consists of replacing the single particle density matrix \(|n\rangle\langle n|\) by its value over the energy shell \[15\].

\[
\hat{\rho}_{\varepsilon_n} = \frac{1}{g(\varepsilon_n)} \sum_{n'} \delta(\varepsilon_n - \varepsilon_{n'}) |n'\rangle \langle n'| = \frac{1}{g(\varepsilon_n)} \delta(\varepsilon_n - h).
\]

An asymptotic expression for \(\hat{\rho}_{\varepsilon_n}\) can then be derived using the semi-classical method by Balian-Bloch for infinite hard wall potentials \[10\] or the Thomas-Fermi (TF) or equivalently Strutinsky averaging method for smooth potentials \[9\].

Recognising that the two body wavefunctions \(|r_1 r_2 n\rangle\) in the pairing matrix elements can be written as \(|r_1 r_2 n\rangle = |r_1 n\rangle \langle n| r_2\rangle\), we can pass to the continuum limit and write for \[11\]

\[
\Delta(\epsilon) = - \int d\epsilon' g(\epsilon') v(\epsilon, \epsilon') \Delta(\epsilon')/2E(\epsilon').
\]

The averaged pairing matrix element is given by

\[
v(\epsilon, \epsilon') = \int d\Gamma dp' f(\epsilon' - p') \delta(R - R').
\]

where \(d\Gamma = dRdp/(2\pi)^3\) and \(v(p)\) is the Fourier transform of the pairing force, \(f = f_+ (R, p)\) is the Wigner transform \[9\].
of \( \hat{\rho}_\varepsilon \) in (4) and a prime on \( \Gamma \) and \( f \) means that all variables should be replaced by primed ones. The size dependence of the gap parameter \( \Delta = \Delta (\varepsilon = \mu) \) is then contained in the corrections to the bulk values of \( g(\varepsilon), v(\varepsilon, \varepsilon'), \) and \( \mu. \)

Let us first evaluate \( \Delta \) for the case of metallic grains and films. The electrons be confined by an infinite hard wall potential of arbitrary shape. As usual in condensed matter physics, we approximate the attractive electron-electron interaction by a delta function pseudo-potential with a cut-off in energy symmetrically on both sides of the Fermi energy \( \mu \) of the order of the Debye frequency \( \omega_D. \) In the bulk the pairing matrix element is therefore given by \( (k - k'|\varepsilon'| - k') = \frac{\pi}{\omega_D} \) for \( |\varepsilon_k - \mu|, |\varepsilon'_{k'} - \mu| \leq \omega_D \) and zero otherwise and \( V \) is the volume of the system. For a finite size grain our main task will be to evaluate the pairing matrix elements (4) for this case. The expression of the level density \( g(\varepsilon) \) in terms of volume, surface, and curvature contributions is well known since long [16]. For the matrix elements we also will employ the Balian-Bloch method [16] using the method of images. To lowest order the distribution functions in (4) are given by \( f_\varepsilon(R, p) \propto \delta (\varepsilon - \hbar^2 p^2 / 2m) \) which is the bulk expression. In order to obtain the correction term, we transform back into coordinate representation, \( f_\varepsilon(R, p) \rightarrow \rho_\varepsilon(r, \varepsilon') \), and then replace \( \varepsilon' \) by \( -\varepsilon' \), the \( z \)-direction being the one perpendicular to the surface. Back into phase space one obtains, \( f_\varepsilon(R, p) = g(\varepsilon)^{-1} \delta (\varepsilon - \hbar^2 p^2 / 2m + \delta f) \) with

\[
\delta f = -\delta (p_z) \frac{2m/\hbar^2}{k_z(p_x, p_y)} \cos (2Rk_z(p_x, p_y))
\]

where \( k_z(p_x, p_y) = \left( \frac{2m}{\hbar^2} \left( \varepsilon - \frac{k_z^2}{2m} (p_x^2 + p_y^2) \right) \right)^{1/2} \). Since \( f_\varepsilon(R, p) \) is normalized to unity, one obtains from (5), in integrating over phase space, the classical result for the level density \( g(\varepsilon) = \frac{1}{4\pi^2} \left( \frac{2m}{\hbar^2} \right)^{1/2} \sqrt{\varepsilon V - \frac{k_F}{4\pi^2} \frac{2m}{\hbar^2}} \) [16]. An important point to be realised is that the volume \( V \) and surface \( S \) correspond to the borders of the hard wall. Since the density is diffuse at the surface, the relevant matter volume \( V_M < V \) is therefore given by the wall delimitation which encloses the correct number of particles. The relations between \( V, S \) and \( V_M, S_M \) are worked out in [12] and are to lowest order given by \( V = V_M + \frac{3\pi}{8k_F} S_M + \ldots \) and \( S = S_M + \ldots \). The level density at the Fermi energy then becomes:

\[
g_F = g(\varepsilon = \mu) = \frac{V_M}{4\pi^2} \frac{2m}{\hbar^2} k_F(1 + \frac{\pi}{8k_F} \frac{S_M}{V_M} + \ldots) \quad (6)
\]

We remark that the sign of the surface term is now positive, that is, for a given volume \( V_M \) the level density is enhanced by the presence of a diffuse surface which, in fact, is the usual situation. With (5) and the definition of \( g(\varepsilon) \) it is, in considering that \( (\delta f)^2 \) also contributes to order \( \frac{S}{V} \), straightforward to evaluate the pairing matrix-element (4). In the case of our delta force, its Fourier transform is a constant and one obtains,

\[
v(\varepsilon, \varepsilon') = -\frac{v_0}{V_M} \left( 1 + \frac{\pi}{4} \frac{\min(k_x, k_y)}{k_x k_y} \frac{S_M}{V_M} + \ldots \right)
\]

We therefore see that, contrary to the level density, the matrix element \( v_F = v(\mu, \mu) \) diminishes in absolute size in the presence of a surface. All ingredients are now prepared and one can solve the gap equation (3) for instance numerically. However, there exists a well known and accurate analytical solution which is more interesting [18]. The result is \( \Delta = 2\omega_D \exp \left( \frac{1}{v_F g_F} \right) \). Inserting \( g_F \) from (6) and \( v_F \) from (4) into the above expression, we notice that the product \( v_F g_F \) does not depend on the surface. However, one also has to account for the compression effect due to the surface tension which increases the chemical potential or respectively the Fermi momentum, and thus \( g_F \). Finally this leads to an enhancement of the gap for low system sizes. Elaborating one obtains \( k_F = k_F^B \left( \frac{1 + \frac{1}{8} \frac{S_M}{V_M} \frac{2m}{\hbar^2}}{1} \right) \), where \( k_F^B \) stands for the bulk value. Inserting into the expression for the gap one obtains

\[
\Delta = \Delta_B e^{-\frac{v_F g_F}{V_M} \frac{2m}{\hbar^2} \frac{S_M}{V_M}},
\]

where \( v_F^B \) and \( \Delta_B \) stand for bulk values. One clearly sees that the gap becomes enhanced as the size of the system decreases.

It is fortunate that formula (8) can be tested on a very early quantum mechanical solution of (1) for a slab [12]. In this case one has \( \frac{S_M}{V_M} = \frac{2L}{\hbar} \) where \( L \) is the film thickness. In [12] the constants in (8) were chosen \(-v_F^B g_F^B = 0.3 \) and \( k_F^B = 0.84 \times 10^6 \text{ cm}^{-1} \). It can be seen from Fig.1 that our pocket formula passes on average well through the quantum mechanical values [12].

![FIG. 1: Dependence of the gap, for the case of a superconducting homogeneous film, on the film thickness \( L \). The saw tooth line corresponds to a quantum mechanical calculation [12], whereas the smooth curve corresponds to formula (8). The horizontal line represents the bulk value \( \Delta_B \) for Aluminium. The dots represent the center of gravity of the triangles in which they are lying (a crude way to estimate an average of the quantal results).](image-url)
In refs. 2, 3, 4, 5 it is indicated that in the case of Al grains one obtains, with respect to the bulk, an enhancement for the critical temperature $T_c$ by roughly a factor of two for a grain diameter of 45 Å. For a spherical grain with $V_M = \frac{4}{3} \pi R^3$, one obtains $S_M = \frac{4}{3} \pi R^3$. However, grains are rather pancake shaped than spherical 2, 19. For an oblate ellipsoid with short diameter half the one of a sphere with the same volume the increase of $S_M/V_M$ is 44 %. Probably grains are even triaxial (see ref. 19, fig.2) and we take $S_M/V_M = 9/(2R)$ which corresponds to a 50 % increase over the spherical case. Taking in 8 the bulk values for Al that is $k_B^2 = 1.75 \text{Å}^{-1}$ and $-\nu_F^2 g_p^2 = 0.168$, we obtain from 8 for $\Delta/\Delta_B$ an enhancement $\sim 30 \%$ at $2R \sim 45 \text{Å}$ which is a sizeable fraction of the experimental value. However, in such small grains the electron levels are discrete and it is well known 10 that the gap equation has no solution, if the average level distance $d \gg \Delta_B$. We therefore solved the gap equation 11 for the picked fence model (equally spaced levels with Kramers degeneracy) 11 for $\omega_D = 395 \text{K}$ which is the value for Al. The number of levels $n_W$ in the window $2\omega_D$ was estimated to be i) $n_W = 2\omega_D g_p^2$ if we take only the lowest order term in 6 and ii) $n_W = 2\omega_D g_F^2$ when including the surface correction to the level density (and the one coming from $\mu$, see above). For the dimensionless interaction constant we take $-\lambda = \nu_F g_F = \nu_F^B g_F^B \left(1 + \pi^2 \frac{3}{8} \frac{S_M}{V_M}\right)$, with $\nu_F^B g_F^B$ as above. In this way we also can calculate $\Delta/\Delta_B$ quantally in the picked fence model. We find that $\Delta/\Delta_B$ raises from $\Delta/\Delta_B = 1$ for $R = \infty$ to $\Delta/\Delta_B \sim 1.2$ at $2R \sim 60 \text{Å}$, following quite accurately our pocket formula. For smaller grain sizes the solution of the gap equation quickly breaks down, the critical size occurring at $2R_c \approx 40 \text{Å}$. The situation is summarized in Table 1. It therefore seems within our schematic model that one can only reach a moderate enhancement of 20% - 30% depending on whether or not one believes into a continuation of the increase into the pair-fluctuating regime. Several comments are, however, in order: Equal level spacing is the most unfavorable situation which can exist. Usually a certain percentage of grains have some symmetries which can enhance the gap (see ref. 20). Therefore on average the gap is larger than the one we have calculated and correspondingly $R_c$ is smaller. However, a precise estimate of the effect is difficult. The gap can also be calculated from the exact solution of the picked fence model (see 21). It turns out that this “quantal” definition of the gaps yields, around the phase transition region, substantially larger values than those from the mean field BCS theory, again enhancing the ratio $\Delta/\Delta_B$. The quantal values of $\Delta$ also can be obtained for sizes quite a bit smaller than $R = R_c$ of BCS theory. We therefore think to have isolated an important enhancement mechanism of pairing in metallic nano-grains stemming from the presence of a surface. Other effects, like e.g. the size dependence of the phonon spectrum, should be taken into account to obtain quantitative agreement with experimental data.

In nuclear physics it is well known since decades that pairing is stronger in lighter nuclei than in heavier ones. An empirical formula $\Delta = 12/\sqrt{A}$ with $A = N + Z$ the sum of neutron ($N$) and proton ($Z$) numbers had been used in the past to fit the data 8, 9. However, more recently Satula et al. 22 pointed out that the data used so far to extract the gap values were overestimated and contaminated by the Jahn-Teller effect 22. A new analysis using the filter $\Delta = \frac{1}{2} [E_{0}^{N+1} + E_{0}^{N-1} - 2E_{0}^{N}]$ for neutron number $N$ odd only, $E_{0}^{N}$ being the measured binding energies of nuclei, revealed that the mass number dependence of $\Delta$ is substantially weaker than the $12/\sqrt{A}$-law. In nuclear physics it is common use to solve the gap equation (1) either, as for the metallic grains, also using a $\delta$-force pseudo-potential with a cut-off 8, 9 or more sophisticated finite range forces are employed for the matrix elements in (1) not necessitating any cut-off. One of the best tested and successful forces of the latter type is the Gogny D1S force 23. In principle for nuclei it is more appropriate to work with smooth potentials like the Woods Saxon or harmonic oscillator potentials and to use for the average density matrix on the energy shell (3) the well

### Table 1: Number of levels in the window ($n_W$), size ($2R$), ($2R$) and gap ($\Delta$), ($\Delta$) without and with surface correction, respectively. The gap obtained using eq. (8) is also given.

| $n_W$ | $2R$ [Å] | $2R$ [Å] | $\Delta$ [K] | $\Delta$ [K] | eq. (8) [K] | $\Delta$ [K] |
|-------|-----------|-----------|-------------|-------------|-------------|-------------|

known Wigner-Kirkwood $\hbar$-expansion \cite{3}. This procedure is, however, more cumbersome and does not lead to such a handy formula as \cite{3}. For space reason we cannot present this here and it will be published separately in the future. For the time being we will also use \cite{3} for finite nuclei as a generic formula. In nuclear physics the convention is such that $-\nu^2_B = \frac{1}{2} M$ and $g_B^2 = \frac{1}{2} \frac{\pi}{\hbar^2} a$ where the level density parameter $a = \frac{k_B^2}{h^2} \times 2\pi \hbar^2 A \text{MeV}^{-1}$. An average value from Skyrme and Gogny forces is $a \sim \frac{4}{A} \text{MeV}^{-1}$. A typical value for $G$ which can be found in the literature \cite{24} is $G = \frac{4}{A} \text{MeV}$. We also checked, using the methods of \cite{15}, that this latter value is compatible with the Gogny D1S force \cite{23}.

On average nuclei are spherical and then $\frac{S_{YM}}{r_0^2} = \frac{3}{4} \pi$ where $R = r_0 A^{\frac{1}{3}}$ is the nuclear radius. The product $k_B^2 r_0 = \left(\frac{9 \pi}{8}\right)^{\frac{1}{2}}$ is a universal number and then, besides $\Delta_B$, all constants in \cite{5} are fixed also for the nuclear case. The bulk value of the gap is a quantity which in nuclear physics is quite uncertain because the mass number range of nuclei is too small to extrapolate to infinite nuclear matter without the guidance of a reliable formula. We expect \cite{5} to be such an expression which allows to pin down $\Delta_B$ within certain limits. In Fig.2 a we show that a good fit to the data with the above values for $a$ and $G$ is obtained with $\Delta_B = .37 \text{MeV}$. Using for $a = \frac{4}{A} \text{MeV}^{-1}$ which is obtained with $m = m^*$ and which is the standard Fermi gas value used in phenomenological models, the fit yields $\Delta_B = .45$. This gives a slightly flatter but still acceptable value than the one shown in Fig.2 and shows that formula \cite{5}, for the nuclear case, is quite robust. These values for $\Delta_B$ are of the same order of magnitude as the asymptotic value $\Delta_B = 0.58 \text{MeV}$ calculated from the D1S force \cite{23}. In Fig. 2 the $A$-dependence has been converted into an $N$-dependence via the relation $A - N = A / (1.98 + 0.0155 A^*)$, which defines the valley of stability of the nuclear chart \cite{23}. Therefore for nuclei the pocket formula \cite{5} gives a very satisfying reproduction of the data and we thus conclude that it contains the essentials of the physics.

In conclusion, we isolated in this work an important and generic enhancement factor of pairing in finite Fermi systems. This stems from the surface corrections to their respective bulk values of level density, pairing matrix element, and chemical potential. We derived a pocket formula for the enhancement factor $\Delta_a / \Delta_B$ which is very general and depends exponentially on the ratio surface to volume of systems of arbitrary shape. It remains valid for level spacings $d \leq 1.4 \Delta$ because for larger spacings the solution of the gap equation breaks down. Our theory explains satisfactorily the average experimental mass number dependence of nuclei. For Al grains we obtain within the picket fence model a maximum enhancement of $\Delta_a / \Delta_B \sim 1.2$ at a grain diameter of $\sim 6 \text{nm}$. We checked that the situation is similar for the case of Sn grains \cite{19}. This estimate is based on BCS theory. We, however, argue that in a more realistic theory the corresponding gap may exist for smaller grains yielding a more important fraction of the experimental results. Other effects mentioned above can give additional enhancements. Studies in this direction are planned for the future.
