Similar effects on murine haemopoietic compartment of low dose rate single dose and high dose rate fractionated total body irradiation. Preliminary results after a unique dose of 750 cGy

Department of Radiotherapy, Institut Gustave-Roussy, 94805 Villejuif, France.

Summary This study was designed to compare two different modalities of TBI which are currently used in clinical practice. The same dose of 750 cGy was given to CBA mice either in a single dose at a low dose rate (4 cGy min⁻¹) (STBI) or in a fractionated regimen (six fractions of 125 cGy three times a day) at a higher dose rate (25 cGy min⁻¹) (FTBI). After TBI completion we simultaneously studied the in vivo radiation response of bone marrow cells, two murine bone marrow clonogenic cells (CFU-S and GM-CFC) and peripheral blood lymphocytes and granulocytes for a period of 1 month. The percentage of spleen erythroidic and granulocytic colonies was also determined. No significant differences were observed between the two groups in the first 48 hours after irradiation except in bone marrow cell numbers, probably due to differences in the overall treatment time between the two TBI schedules. After the first 48 hours the repopulation patterns of the different cells were very similar in both groups. These findings suggest that the different dose rates and fractionation used in this study caused similar radiation damage to the murine haemopoietic system. Moreover, no significant repopulation occurred during the longer overall treatment time of the fractionated regimen. These preliminary results must be corroborated with a larger range of doses before any firm conclusion can be drawn.

Materials and methods

Animals

Experiments were carried out on CBA mice (3–4-month-old males). The animals were housed under specific pathogen free conditions, and were randomly allocated to treated and untreated control groups. Three to four experiments were done for each radiation schedule (single dose and fractionated TBI).

Irradiation

Each animal was confined to a separate compartment of a lucite container which housed 15 animals. Animals of the group were treated in a similar manner for the same amount of time, but were not given radiation. Irradiation was delivered with a Cobalt source (EPSI, Clamart, France). A dose of 750 cGy was given to mice since previous experiments had shown this dose to be just below the LD₅₀/₃₀. Total body irradiation was delivered either in a single dose (STBI) at 4 cGy min⁻¹ or in multiple fractions (three daily fractions of 125 cGy, 3 h apart) at a higher dose rate of 25 cGy min⁻¹ (FTBI). The different dose rates were made possible by shielding the source with cerrobend and lead blocks. At different times after the completion of the radiation, three mice from the irradiated and sham groups were killed by cervical dislocation.

CFU-S assay

Bone marrow cells were obtained by flushing the medullary cavity of the tibia and femur with cold 199 medium. Cells were counted using a Coulter counter and their viability was assessed by the trypan blue dye technique. Cell dilutions were selected to yield 10–20 colonies per spleen. Cells were injected intravenously to 10 lethally irradiated recipient mice (CBA mice given 9 Gy using a 60Co unit). Nine days later the recipient mice were killed and their spleen fixed in Bouin’s solution. Macroscopic colonies were then counted, the number of colonies surviving per leg was determined and the surviving fraction was calculated by comparison with unirradiated controls done on the same day.

Recently fractionated total body irradiation (FTBI) schedules have been favoured over single dose total body irradiation (STBI) because they are thought to increase the differential effect between lung and haemopoietic tissues (Peters, 1980; Peters et al., 1979). Lung cells are capable of repairing radiation damage as opposed to haemopoietic stem cells thought to have no or a very limited capacity for repair (Evans et al., 1988; Frindel et al., 1972; Glasgow et al., 1983; Hendry, 1985; Krebs & Jones, 1972; Tarbell et al., 1987; Travis et al., 1985). However, some authors have shown that dose rate and/or fractionation could play an important role in the survival of haemopoietic stem cells (Hageneck & Martens, 1981; Peacock et al., 1986; Puro & Clark, 1972; Song et al., 1987) and suggested that these cells might be capable of repairing radiation damage. This could explain why in clinical practice a higher incidence of graft rejection and leukaemia relapses was observed in patients given T cell depleted bone marrow graft and a fractionated TBI instead of a single dose TBI (Guyotat et al., 1987; Patterson et al., 1986).

In our institution over 100 total body irradiations are performed annually and are delivered either in a single fraction at a low dose rate (4 cGy min⁻¹) over 4 h or in multiple fractions (6–11) at a relatively high dose rate (25 cGy min⁻¹) over a few days (3–4). We therefore decided to compare the simultaneous influence of dose rate (HD or LD), delivery schedule (single dose/fractionation) and overall treatment times (4 h/3–4 days) used in clinical practice in an animal model. This type of comparison has never been attempted to our knowledge. We studied the survival of the bone marrow pluripotent CFU-S stem cells and their differentiation into erythroidic or granulocytic colonies. The survival of bone marrow clonogenic GM-CFC cell and of peripheral blood granulocytes and lymphocytes was also analysed. The early response to irradiation (the first 48 h) and subsequent repopulation over a period of 1 month are reported.
Histology
Recipient mice spleens were embedded in paraffin, sliced and stained according to the modified eosin-haematoxylin-Safran method. The proportion of erythrocytic, granulocytic, megakaryocytic and undifferentiated colonies were determined and the ratio E/G (erythrocytic over granulocytic colonies) calculated.

GM-CFC assay
According to Worton's technique (Worton et al., 1969) cells were plated in tissue culture dishes with methylcellulose, horse serum and colony stimulating factor (CSF) prepared according to Sheridan's technique (Sheridan & Metcalf, 1973). Bone marrow cell dilutions were selected to yield about 50 colonies. After 7 days at 37°C in a 5% CO₂ humidified atmosphere, colonies of more than 50 cells were counted. The surviving fraction was calculated by comparison with unirradiated controls done on the same day.

Blood counts
Irradiated and control mice were bled from the retro-orbital sinus. Blood was pooled in a heparinised tube. The white blood cells (WBC) were counted on a Coulter counter and a differential was obtained by counting granulocytes and lymphocytes on a stained smear under a microscope. The results were expressed as a percentage of control values.

Statistical tests
Three to four experiments were performed for each single dose and fractionated schedule. The results were compared using Student's t test.

Results
No deaths occurred among the irradiated animals during the period of observation. Table I shows that bone marrow cell numbers were significantly lower in the FTBI group the first day after irradiation but later the values were similar in both groups and returned to pre-treatment values by the third week. Figure 1 shows that the surviving fraction of CFU-S/leg was similarly reduced by 2.8 logs the first day in both groups, and subsequent repopulation brought the values back to normal, 2–3 weeks after TBI. The percentages of granulocytic and erythrocytic splenic colonies are given in Table II. In both groups a similar trend towards an increase in granulocytic differentiation and a decrease in erythrocytic differentiation was observed the first day with a return to normal values 2–3 weeks later. The surviving fraction of GM-CFC/leg was reduced in both groups by 2.5 logs during the first two days. Afterwards repopulation was similar in both groups except on day 7 when the values were significantly higher in the FTBI group (Figure 2). In both groups, concentrations of peripheral blood granulocytes increased slightly the first day, then decreased moderately before returning to normal values by day 14 with a slight overshoot later. A considerable decline in lymphocyte numbers occurred immediately after irradiation and subnormal values were reached by the end of the observation period in both groups (Figure 3).

Discussion
Animal experiments were set up to verify whether TBI schedules, commonly used in clinical practice, had different or identical efficacy on the murine haemopoietic system. Efficacy was difficult to predict because in each TBI schedule one radiation parameter may have cancelled out the effect of the other. For example low dose rate versus single fraction in

| Table I Bone marrow cell numbers |
|----------------------------------|
| Days after end of radiation treatments | 1 | 2 | 7 | 14 | 21 | 28 |
| Single dose (STBI) | 22±3* | 10±0.2 | 22±6 | 75±10 | 100±15 | 100±7 |
| Fractionated (FTBI) | 9.5±1.5* | 12±1 | 36±8 | 65±10 | 110±10 | 130±20 |

Values are percentages determined by comparison with controls done the same day, ± s.d. *Significantly different values between the 2 groups.
the STBI schedule, high dose rate versus fractionation in the FTBI schedule.

Radiation damage repair capacity of CFU-S and GM-CFC clonogenic cells is usually considered to be limited or non-existent (Evans et al., 1988; Glasgow et al., 1983; Tarbell et al., 1987) yet some other authors have suggested that CFU-S and/or GM-CFC are capable of repairing radiation damage (Peacock et al., 1986; Puro & Clark, 1972; Song et al., 1987). If such is the case then low dose rate and fractionation would allow some radiation damage repair in clonogenic cells during STBI and FTBI respectively. On the other hand a single fraction and a relatively high dose rate would preclude repair during STBI and FTBI respectively. The problem is further compounded by a factor which is often overlooked, namely, different overall treatment times (4 h versus 3–4 days). A longer overall treatment time might allow more haemopoietic cell repopulation than a shorter one.

The results showed that the same dose of 750 cGy delivered either as a single fraction at a low dose rate (4 cGy min⁻¹) over 3 h or in several fractions at a higher dose rate (25 cGy min⁻¹) over a longer period of time (2 days) gave similar early effects on the murine haemopoietic compartment. Furthermore, a month later there was still no significant difference between the two groups although slightly higher values were observed in the FTBI group.

The early effects after the end of radiation treatments (i.e. the first 48 h) were similar in both groups for all cells except for bone marrow cells. CFU-S and GM-CFC clonogenic cells were reduced immediately after radiation in both groups by 2.8 and 2.5 logs respectively. Differences in dose rates between the 2 schedules (4 cGy min⁻¹ versus 25 cGy min⁻¹) were not very large and therefore it is likely that they played a very minimal role, as previously shown in some authors (Frindel et al., 1972; Glasgow et al., 1983; Tarbell et al., 1987; Travis et al., 1985; Evans et al., 1988). The similar early effects found in both groups suggest first, that fractionation did not play any role in the sparing of the CFU-S and GM-CFC clonogenic cells, and second that no significant repopulation took place during the fractionated TBI. These conclusions are further supported by the fact that between the two groups no significant differences in the numbers of CFU-S and GM-CFC were observed during the 1 month observation period.

The first day after irradiation, peripheral blood granulocyte numbers were slightly increased in both groups. This transient increase was probably due to a release of mature granulocytes from bone marrow as shown by Harris (1959) and Dutreix et al., (1987). Differences in bone marrow cell numbers the first day after irradiation were probably due to different treatment durations between the two groups (3 h for the STBI groups and 36 h for the FTBI group); a longer treatment time allowing the elimination of doomed cells.

The pattern of repopulation of bone marrow cells, and CFU-S was similar in both groups and lead to a complete recovery 1 month later. This finding suggests that bone marrow clonogenic cells and possibly their microenvironment, thought to be critical in haemopoietic recovery (Hendry, 1985; Schofield & Dexter, 1982) were similarly affected by the two different radiation protocols. However, a much longer follow-up is warranted to determine damage caused to the microenvironment by the different radiation treatments.

Both irradiations induced the same changes in clonogenic cell differentiation resulting in an early increase in granulocyte colonies and a concomitant decrease in erythrocyte colonies as already reported by Frindel et al. (1980). The E/G ratios were significantly decreased in both groups, soon after irradiation with a return to normal values by the end of the second week (Table II).

GM-CFC clonogenic bone marrow cells in both groups showed a similar repopulation pattern except on day 7 when significantly different surviving fractions were observed. This finding might be due to an earlier start in either GM-CFC repopulation or CFU-S differentiation towards GM-CFC progenitors in the FTBI group. However, it cannot be excluded that the difference is purely artefactual since the analysis was performed 9 days after the start of the fractionated radiotherapy and only 8 days after the start of the single dose radiotherapy.

Repopulation of the peripheral blood granulocytes was similar in both groups with a slight overshoot by the end of the month for which there is no clear explanation. On the other hand lymphopenia was still present at the end of the observation period in both groups suggesting that both types of irradiation are equally immunosuppressive.

In conclusion, although the underlying mechanisms are complex and not fully understood, our study indicates that

fractionated and single dose TBI have similar effects on the murine haemopoietic system. It suggests that both TBI regimens could be given to patients for bone marrow transplantation provided that radiation damage to the lung is not increased by either of the two schedules. However, these results should be corroborated with a larger range of doses for firm conclusions to be drawn and is the subject of an ongoing study.
